(Received 14 April 2000; published 12 October 2000)

From a fit to the experimental data on the $b\bar{b}$ fine structure, the two-loop strong coupling constant is extracted. For the $1P$ state the fitted value is $\alpha_s(\mu_1)=0.33\pm0.01$ (exp) $\pm0.02$ (th) at the scale $\mu_1=1.8\pm0.1$ GeV, which corresponds to the QCD constant $\Lambda^{(4)}_{\text{2-loop}}=338\pm30$ MeV ($n_f=4$) and $\alpha_s(M_Z)=0.119\pm0.002$. For the $2P$ state the value $\alpha_s(\mu_2)=0.40\pm0.02$ (exp) $\pm0.02$ (th) at the scale $\mu_2=1.02\pm0.02$ GeV is extracted, which is significantly larger than in the previous analysis, but about 30% smaller than the value given by the standard perturbation theory. This value $\alpha_s(1.0)\approx0.40$ can be obtained in the framework of the background perturbation theory and appears to be compatible with the freezing of $\alpha_s(\mu)$. The relativistic corrections to $\alpha_s$ are found to be about 15%.

I. INTRODUCTION

The bottomonium spectrum is one of the richest among all known mesons and its levels were measured with high precision [1]. These data about $b\bar{b}$ states have been intensively studied in different theoretical approaches, in particular, to determine the QCD strong coupling constant $\alpha_s(\mu)$ at different energy scales $\mu$ from the level differences [2–10]. At present, however, there is no clear picture of which are the exact values of $\alpha_s(\mu)$ for the $b\bar{b}$ levels and how they are changing from the ground state to the excited ones. There are several reasons for this.

First of all, there is no experimental information on the $\eta_b(nS)$ masses and therefore $\alpha_s(\mu)$ cannot be directly determined from the $b\bar{b}$ hyperfine splittings in $S$-wave states. Second, to describe the fine structure splittings in the $P$-wave states, different energy scales $\mu$ were used in different theoretical analyses [4–7]. In Ref. [4] $\alpha_s(\mu)=0.33$ ($\mu=3.25$ GeV) was taken for all $b\bar{b}$ $S$- and $P$-wave states, while in Ref. [5] $\mu$ was chosen to be equal to the $b$ quark mass, $m_b$ with either $m=4.6$ GeV or $m=5.2$ GeV. The fitted values of $\alpha_s(\mu)$ were found to be $\alpha_s(m)=0.22–0.27$ [5] and for the $2P$ state $\alpha_s(\mu)$ appeared to be smaller than for the $1P$ state.

An important step to clarify this problem was taken in Refs. [6,7] where the low-lying bottomonium states, $1S$, $2S$, and $1P$ were investigated. It was observed there that the scale $\mu$ is a decreasing function of the principal quantum number $n, \mu=2(na)^{-1}$ where $a$ is a Coulomb-type radius. Therefore, $\mu$ is found to be equal for the $2S$ and $1P$ states and the values $\mu=1.7$ GeV, $\alpha_s(1.7)=0.29$, were determined from the fine structure splittings of $\chi_b(1P)$. Also, $\alpha_s(\mu)$ is larger for excited states with a larger radius of the system, thus indicating that for a bound state the characteristic scale $\mu$ is determined by the size, but not by the momentum of the system. One of our main goals here is to check this important statement for the $2P$ state, $\chi_b(2P)$, which cannot be studied in the framework of the approach developed in Refs. [6,7].

In the present study of the $1P$ and $2P$ $b\bar{b}$ states we shall try to answer the following questions: What are the values of $\alpha_s(\mu)$ for the $2P$ and the $1P$ states? Do the extracted values of $\alpha_s(\mu)$ correspond to the existing experimental data on $\alpha_s(M_Z)$ and $\Lambda^{(4)}$? How does $\alpha_s(\mu)$ depend on the relativistic corrections to the wave functions in bottomonium? How sensitive are the extracted values of $\alpha_s(\mu)$ to the $b$ quark pole mass and the parameters of the static interaction?

II. PERTURBATIVE RADIATIVE CORRECTIONS

It is well known that one cannot describe the fine structure splittings in heavy quarkonia without taking into account the second order radiative corrections [4–7,10]. In coordinate space, perturbative static and spin-dependent potentials in the modified minimal subtraction ($\overline{MS}$) renormalization scheme were obtained in Refs. [2,3]. From the potentials given there one can immediately find the matrix elements of the spin-orbit and the tensor potentials $a\equiv\langle V_{LS}(r)\rangle$, $c\equiv\langle V_T(r)\rangle$. Below we give their expressions for a number of flavors $n_f=4$, valid for the $b\bar{b}$ system:

$$a_p=a_p^{(1)}+a_p^{(2)},$$

$$a_p^{(1)}=\frac{2\alpha_s(\mu)}{m^2}\langle r^{-3}\rangle,$$

$$a_p^{(2)}=\frac{2\alpha_s^2(\mu)}{\pi m^2}\left[\frac{25}{6}\ln\left(\frac{\mu}{m}\right)+A\right]+\frac{13}{6}\langle r^{-3}\ln mr\rangle,$$

and for the perturbative part of the the tensor splitting $c_p$,

$$c_p=c_p^{(1)}+c_p^{(2)},$$

$$c_p^{(1)}=\frac{4}{3}\frac{\alpha_s(\mu)}{m^2}\langle r^{-3}\rangle,$$
The function
\[ c_p^{(2)}(\mu) = \frac{4}{3} \frac{\alpha_s^2(\mu)}{\pi m^2} \left( r^{-3} \left( \frac{25}{6} \ln \frac{\mu}{m} + B \right) + \frac{7}{6} r^{-3} \ln m r \right). \]  

(4)

Here the constant \( A = \frac{13}{6} \gamma_E + \frac{7}{36} = 1.44508 \) and \( B = \frac{7}{12} \gamma_E + \frac{11}{12} = 3.42342 \).

For our analysis it is convenient to introduce a linear combination of the matrix elements \( a \) and \( c \) as was done in Ref. [10]: \( \eta = \frac{1}{2} c - a \). Its perturbative part \( \eta_p \) is

\[ \eta_p = \frac{3}{2} c_p - a_p = \frac{3}{2} c_p^{(2)} - a_p^{(2)} = \frac{2 \alpha_s^2(\mu)}{\pi m} f_4. \]  

(5)

The factor \( f_4 \) in Eq. (5) can be found from Eqs. (2) and (4),

\[ f_4(nP) = \frac{1}{m} \left[ 1.97834 \left( r^{-3} \right)_{nP} - r^{-3} \ln m r \right]. \]  

(6)

For the fine structure analysis it turns out to be very important that the combination of matrix elements \( f_4 \) does not depend on the energy scale \( \mu \). Later, it will also be shown that \( f_4 \) has the largest relativistic correction (about 35%) compared to other matrix elements and depends weakly on the parameters of the static interaction and on the mass of the \( b \) quark.

Here we give also the ratio of the perturbative matrix elements \( a_p / c_p = \xi_p \). In the Coulomb case (one-gluon exchange) \( \xi_p \) is equal to 3/2, but in the one-loop approximation this ratio has a small negative correction:

\[ \xi_p(nP) = \frac{a_p(nP)}{c_p(nP)} = \frac{3}{2} \left( 1 - \frac{\alpha_s(\mu)}{\pi} \frac{f_4(r_m)}{r^{-3}}\right). \]  

(7)

The function \( f_4(r_m) \) in Eq. (7) is defined by the expression (6). We shall see later that the one-loop correction to \( \xi_p(nP) \) turns out to be very small (\( \approx 3\% \)) and with the use of the expression (7) it is not possible to explain the existing experimental values \( \xi_{exp}(nP) \) (they are given in Sec. IV).

Therefore it is of great importance to take into account the nonperturbative contributions to the splittings \( a \) and \( c \) which are considered in the next section. We would like to note here that significant corrections of higher order to \( \xi_p \), Eq. (7), cannot be excluded, still, these corrections have not been calculated until now.

### III. NONPERTURBATIVE CONTRIBUTIONS

In addition to the perturbative terms, Eqs. (2), (4), the tensor and spin orbit splittings have in general nonperturbative contributions: \( a = a_p + a_{NP} \), \( c = c_p + c_{NP} \). The nonperturbative part of the spin-orbit potential \( V_{LS}^{NP}(r) \) can be defined with the use of three potentials: the nonperturbative static potential \( \epsilon(r) \) and the so-called \( V_1 \) and \( V_2 \) potentials [11]

\[ V_{LS}^{NP}(r) = \frac{1}{m^2 r} \left( \frac{1}{2} \frac{d \epsilon}{dr} + \frac{1}{2} \frac{d V_1^{NP}}{dr} + \frac{1}{2} \frac{d V_2^{NP}}{dr} \right). \]  

(8)

Each of these potentials can be expressed through two gauge invariant vacuum correlators \( D(x) \) and \( D_1(x) \) \( (x = \sqrt{\lambda^2 + \nu^2}) \) [12–16]:

\[ \frac{d \epsilon}{dr} = 2 \int_0^\infty d \nu \int_0^\nu d \lambda \ D(\sqrt{\lambda^2 + \nu^2}) \]

\[ + r \int_0^\infty d \nu \ D_1(\sqrt{\lambda^2 + \nu^2}), \]  

(9)

\[ \frac{d V_1^{NP}}{dr} = -2 \int_0^\infty d \nu \int_0^\nu \lambda d \lambda \ D(\sqrt{\lambda^2 + \nu^2}) \]

\[ + r \int_0^\infty d \nu \ D_1(\sqrt{\lambda^2 + \nu^2}), \]  

(10)

so that

\[ V_{LS}^{NP}(r \to 0) = \frac{1}{2 m^2 r} \left( \int_0^\infty d \nu \int_0^\nu \lambda d \lambda \left[ -2 + \frac{8 \lambda}{r} \right] D(\sqrt{\lambda^2 + \nu^2}) \right) + 3 r \int_0^\infty d \nu \ D_1(\sqrt{\lambda^2 + \nu^2}). \]  

(12)

Note that in the potential (12) the interference of perturbative and nonperturbative effects was not taken into account. From Eq. (12) one can find the general form of the asymptotic behavior of the spin-orbit potential at large and small distances

\[ V_{LS}^{NP}(r \to \infty) = \frac{-\sigma}{2 m^2 r} + \frac{4}{m^2 r^2} \int_0^\infty d \nu \int_0^\nu \lambda d \lambda \ D(\sqrt{\lambda^2 + \nu^2}), \]  

(15)

with the string tension \( \sigma \) defined as

\[ \sigma = 2 \int_0^\infty d \nu \int_0^\nu \lambda d \lambda \ D(\sqrt{\lambda^2 + \nu^2}). \]  

(16)

In the asymptotics of the potential (15) the contribution of the correlator \( D_1 \) can be neglected because \( D_1(x) \), as well as \( D(x) \), is exponentially decreasing at large distances.
From Eqs. (13) and (15) one can see that \( V_{LS}^{NP}(r) \), defined by Eq. (12), has different \( r \) dependence at small and large distances: it is approaching the Thomas potential at large distances and equal to a positive constant at small distances. The spin-orbit potential turns out to be constant at small \( r \) because in this region the nonperturbative static potential \( \varepsilon(r) \), given by the expression [13,14]

\[
\varepsilon(r) = 2r \int_0^r d\lambda \left( 1 - \frac{\lambda}{r} \right) \int_0^\infty d\nu \, D(\lambda, \nu) + \int_0^r \lambda d\lambda \int_0^\infty d\nu \, D_1(\lambda, \nu),
\]

(17)
is proportional to \( r^2 \)

\[
\varepsilon(r) = r^2 \left( J_0 + \frac{J_1}{2} \right).
\]

(18)
The constants \( J_0 \) and \( J_1 \) were defined in Eq. (14). Note that such a behavior of the nonperturbative static potential \( \varepsilon(r) \sim \text{const.} r^2 \), obtained in an approximation where the interference of the perturbative and nonperturbative contributions was neglected. However, as was shown in Ref. [19], due to the interference the static potential has a universal linear term

\[
\Delta V_{\text{int}} = r \Delta \sigma, \quad \Delta \sigma = \frac{3}{\pi} N_c \alpha_s(q) \sigma.
\]

(19)

Note that this potential is proportional to the strong coupling constant \( \alpha_s \) and it is not small: \( \Delta \sigma \approx 0.6 \sigma \) already at the point \( r = 0.25 \text{ GeV}^{-1} = 0.05 \text{ fm} \) [at \( r = 0.25 \text{ GeV}^{-1} \) \( \alpha_s(q) \approx 0.22 \) because the QCD constant \( \Lambda \) in coordinate space is rather large, \( \Lambda \approx 0.6 \text{ GeV} \) [17]]. This interference potential cannot be deduced from the expression (15) for \( \varepsilon(r) \).

A large nonperturbative contribution to the static potential at small distances was also found in lattice calculations [17] where an essential difference between the static potential on the lattice and the three-loop perturbative potential (at \( r \approx 0.2 \text{ fm} \)) was found. The author suggested to parametrize it as a linear term, \( \sigma^* r \), with very large \( \sigma^* \approx (0.8-1.0) \text{ GeV}^2 \). The theoretical explanation of the appearance of such a large linear (or approximately linear) potential is still not given.

The possibility of a correction of linear type to the static potential at short distances was also discussed in Ref. [18] where it was noticed that due to the saturation (or freezing) of the QCD coupling at small momenta [19,20] (see also Sec. VI).

\[
\alpha_s(q)_{q \to 0} = \frac{4 \pi}{\beta_0} \frac{1}{\ln[(q^2 + m_B^2)/\Lambda^2]}.
\]

(20)

\( m_B \) is the background mass [21]) there is a correction to the perturbative coupling constant \( \alpha_s(q) \) at relatively large \( q \) (or small \( r \)):

\[
\Delta \alpha_s = \alpha_s(q) - \alpha_s(q_{q \to 0}) \approx - \alpha_s(q) \frac{m_B^2}{q^2 \ln(q^2/\Lambda^2)} (q > m_B),
\]

(21)

which is proportional to \( \alpha_s(q) \) and to the background mass \( m_B^2 \). It can be shown that in coordinate space the interference potential, \( \bar{V}_{\text{int}} = -\frac{4}{3} [\Delta \alpha_s(q)/r] \), is behaving almost linearly.

Also in lattice calculations of the potentials \( \varepsilon'(r) \), \( V'_1(r) \), and \( V'_2(r) \) in the region 0.2 fm \( \leq r \leq 1.0 \text{ fm} \) [22,23] it was found that the nonperturbative part of the potential \( V'_2(r) \) is small (compatible with zero) while \( \varepsilon' \) and \( V'_1(r) \) turn out to be practically constant beginning already at distances \( r_0 \approx 0.2 \text{ fm} \). (This value \( r_0 \) is close to the vacuum correlation length \( T_g \) determining the exponential behavior of the correlators \( D \) and \( D_1 \) at \( r \approx T_g \) [24,25]). From these data one can conclude that the nonperturbative spin-orbit potential coincides with the Thomas interaction in the region \( r \approx 0.2 \text{ fm} \) and the same behavior can occur due to interference effects at smaller distances.

Therefore we adopt here the Thomas interaction at all distances and the nonperturbative contribution to the spin-orbit splitting becomes

\[
a_{NP} = \frac{\sigma}{2m^2} \langle r^{-1} \rangle.
\]

(22)

The nonperturbative contribution to the tensor splitting can be found from the vacuum field correlator \( D_1(x) \) [10,21] which was measured in lattice QCD [24,25] and was found to be of exponential form. Then, as was shown in Refs. [10,26,27],

\[
\epsilon_{NP} = \frac{D_1(0)}{3m^2 T_g} \langle r^2 K_0(r/T_g) \rangle = \frac{D_1(0)}{3m^2} J(T_g),
\]

\[
J(T_g) = \frac{1}{T_g} \langle r^2 K_0(r/T_g) \rangle
\]

(23)

where \( T_g \) is the vacuum correlation length. Lattice QCD calculations without dynamical fermions give \( T_g \approx 0.2 \text{ fm} \) and \( T_g \approx 0.3 \text{ fm} \) in the presence of dynamical fermions with four flavors [24]; in Ref. [25] \( T_g \) was found to be 40% smaller.

In Refs. [24] the correlator \( D_1(0) \) in Eq. (23) was shown to be small: lattice calculations in quenched SU(3) theory give \( D_1(0)/D(0) \approx \frac{1}{2} \) and in full QCD with four staggered fermions \( D_1(0)/D(0) \approx 0.1 \), where \( D(x) \) is another vacuum field correlator which mostly determines the confining potential. These two correlators at the point \( x = 0 \) can be expressed through the vacuum gluonic condensate \( G_2 \) (here the vacuum correlators are normalized as in Refs. [12,14]):

\[
D(0) + D_1(0) = \frac{\pi^2}{18} G_2.
\]

(24)

Therefore, the lattice estimate for \( D_1(0)/D(0) \) is 0.1–0.3 and from the relation (24) one obtains
\[
\frac{\pi^2}{180} G_2 \leq D_1(0) \leq \frac{\pi^2}{72} G_2. \tag{25}
\]

Our calculations give the following typical values for the matrix elements \( J(T_p) \): for the 1\( P \) state \( J(T_p) \approx 0.17 \text{ GeV}^{-1} \) and for the 2\( P \) state \( J(T_p) \approx 0.20 \text{ GeV}^{-1} \), if the b quark mass \( m_b \approx 4.8 \text{ GeV} \) and \( T_p \approx 0.2 \sim 0.3 \text{ fm} \) is taken. Then, if the value of the gluonic condensate \( G_2 \approx 0.05 \pm 0.02 \text{ GeV}^4 \) \(^7\) is used, one finds the estimate in quenched QCD

\[
c_{\text{NP}} \approx 0.03 \pm 0.01 \text{ MeV}. \tag{26}
\]

In full QCD an even smaller value is found. This value of \( c_{\text{NP}} \) is much less than both \( |a_{\text{NP}}| \), Eq. (7), and the experimental errors. Therefore it can be neglected in the tensor splitting \( c \) and also in \( \eta_{\text{NP}} = \frac{1}{2} c_{\text{NP}} - a_{\text{NP}}, \) i.e., we take here \( \eta_{\text{NP}} = a_{\text{NP}} \).

### IV. FITTING CONDITIONS

To fit the experimental data

\[
a_{\exp}(1P) = 14.23 \pm 0.53 \text{ MeV},
\]

\[
a_{\exp}(2P) = 9.39 \pm 0.18 \text{ MeV},
\]

\[
c_{\exp}(1P) = 11.92 \pm 0.25 \text{ MeV},
\]

\[
c_{\exp}(2P) = 9.14 \pm 0.25 \text{ MeV},
\]

\[
\xi_{\exp}(1P) = 1.19 \pm 0.06, \quad \xi_{\exp}(2P) = 1.03 \pm 0.05, \tag{27}
\]

the following conditions have to be satisfied:

\[
a_{\text{tot}}(nP) = a_p^{(1)} + a_p^{(2)} - \frac{\sigma}{2m^2} \langle r^{-1} \rangle = a_{\exp}(nP)
\]

\[
c_{\text{tot}}(nP) = c_p^{(1)} + c_p^{(2)} = c_{\exp}(nP). \tag{28}
\]

As seen from Eqs. (2) and (4), the left-hand side of these expressions strongly depend on the normalization scale \( \mu \), but the combination \( \eta \) does not. The fitting condition for \( \eta \) is

\[
\eta(nP) = \frac{2 a^2_\gamma(\mu)}{\pi m} f_4 + \frac{\sigma}{2m^2} \langle r^{-1} \rangle = \eta_{\exp}, \tag{29}
\]

where the experimental values for \( \eta_{\exp}(nP) \) are

\[
\eta_{\exp}(1P) = 3.65 \pm 0.9 \text{ MeV}, \quad \eta_{\exp}(2P) = 4.32 \pm 0.4 \text{ MeV}. \tag{30}
\]

The condition (29) does not depend explicitly on \( \mu \) and can be rewritten as

\[
\frac{2 a^2_\gamma(\mu)}{\pi m} f_4(nP) = \eta_{\exp} - \frac{\sigma}{2m^2} \langle r^{-1} \rangle = \Delta(nP), \tag{31}
\]

hence the strong coupling constant can be expressed as

\[
\alpha_s(\mu) = \sqrt{\frac{\pi m \Delta}{2 f_4}}. \tag{32}
\]

For a chosen interaction and quark mass \( m \), \( \Delta(nP) \) and \( f_4(nP) \) are known numbers and one can immediately determine \( \alpha_s(\mu) \). In general \( \Delta(nP) = \eta_{\exp} + a_{\exp} \) will be larger than for the static linear potential \( (a_{\exp} \) may be even positive) and therefore for the static linear potential the difference \( \Delta(nP) \), as well as the extracted value of the strong coupling constant, has a minimal value.

The extraction of \( \alpha_s(\mu) \) from the condition (32), in general, extremely simplifies the fit and also puts strong restrictions on the possible choice of the normalization scale \( \mu \). Just this condition was exploited in Ref. \(^{10}\) to determine \( \alpha_s(\mu) \) for the 1\( P \) state in charmonium. In charmonium \( \eta_{\exp} \approx 24 \text{ MeV} \) and the typical value of \( \Delta \approx 7 \sim 8 \text{ MeV} \) is not small, so the uncertainty in the extracted value of \( \alpha_s(\mu) \) is about 10\%.

In bottomonium the typical values of \( |a_{\exp}| \) are found to be smaller: \( |a_{\exp}(1P)| = 2.6 \pm 0.2 \text{ MeV} \) (see Table V) and \( |a_{\exp}(2P)| = 1.95 \pm 0.10 \text{ MeV} \) (see Table IV). As a result, the numerical values of \( \Delta(nP) \) to be substituted in Eq. (32) are small:

\[
\Delta(1P) = 1.05 \pm 0.9(\exp) \pm 0.15(\text{th}) \text{ MeV},
\]

\[
\Delta(2P) = 2.4 \pm 0.4(\exp) \pm 0.10(\text{th}) \text{ MeV}. \tag{33}
\]

The theoretical uncertainties in this equation are caused by the uncertainty of the value of \( \alpha_s(\exp) \) in the Thomas interaction. Still, for the 2\( P \) state the total error in \( \Delta(2P) \) is not large, about 20\%, and therefore \( \alpha_s(\mu) \), proportional to \( \sqrt{\Delta} \), can be determined from the condition (32) with an accuracy of about 10\%. Our calculations show also that the matrix element \( f_4 \) in Eq. (32) is practically constant and therefore the theoretical error in Eq. (33) coming from \( f_4 \) is small.

For the 1\( P \) state the experimental error in \( \eta_{\exp} \), Eq. (30), as well as in \( \Delta \), Eq. (33), is large: it comes mostly from the experimental uncertainty in the \( \chi_{\text{br}}(1P) \) mass. Therefore \( \Delta(1P) \) can vary in a wide range: \( 0 \approx \Delta \approx 2.0 \text{ MeV} \) and the relation (32) cannot give an accurate value for \( \alpha_s(\mu) \). Instead, for the 1\( P \) state one needs to use the conditions (28) which are \( \mu \)-dependent and less restrictive.

### V. DEPENDENCE ON SCALE

The second-order perturbative corrections to the spin-orbit and tensor splittings, which are not small, explicitly depend on the scale \( \mu \). In Eqs. (2), (4) \( \ln(\mu/m) \) enters with the large coefficient 25/6 and therefore the choice \( \mu=m \) (causing this logarithm to vanish) can give rise to inconsistent results. Just this choice was taken in Ref. \(^{5}\) where two b-quark masses \( m_b = 4.6 \text{ GeV} \) and \( m_b = 5.2 \text{ GeV} \) were analyzed. We shall discuss here some results of Ref. \(^{5}\).

From the fit in Ref. \(^{5}\) it was obtained that the value \( \bar{\alpha}_s(m) \) extracted from the tensor and the spin-orbit splittings is slightly different and for the 2\( P \) state this difference is increasing. [Here \( \alpha_s(\mu) \) or \( \bar{\alpha}_s(\bar{\mu}) \) denotes the fitted (ex-
traced) value of the strong coupling constant.]

Also, for the 2P state \( \tilde{\alpha}(5.2) = 0.26 \pm 0.01 \) is a bit larger than \( \alpha_s(4.6) = 0.25 \pm 0.01 \) for the smaller b-quark mass, in contradiction with the standard behavior of the running coupling constant \( \alpha_s(q^2) \). In all cases considered in Ref. [5] the extracted value, \( \tilde{\alpha}_s(m) = 0.25 \pm 0.27 \), turned out to be about 20\% larger than the values \( \alpha_s(4.6) \) and \( \alpha_s(5.2) \) calculated with the conventional value of \( \Lambda^{(4)} \) Eq. (34): \( \alpha_s(4.6) = 0.22 \pm 0.01 \), \( \alpha_s(5.2) = 0.21 \pm 0.01 \).

In the calculations that follow, it will be easy to compare our results with those from Ref. [5] because in both cases the same perturbative interaction and linear potential \( \sigma \tau \) were used. However, the calculations of Ref. [5] were done in the nonrelativistic case (for fixed \( \sigma = 0.2 \) GeV\(^2\) and two b-quark masses). Here both relativistic and nonrelativistic cases will be considered and \( \sigma, m, \) and \( \alpha_{\text{eff}} \) of the Coulomb potential will be varied in a wide range. From our analysis it will be clear that the inconsistencies in the \( \tilde{\alpha}_s(\mu) \) behavior mentioned above, are related to the \textit{a priori} choice \( \mu = m \) made in Ref. [5].

At this point it is worthwhile to note that at present the QCD constant \( \Lambda^{(4)} \) is well known for \( n_f = 5 \), because \( \alpha_s(M_z) = 0.119 \pm 0.002 \) is established from different experiments: \( \Lambda^{(5)}(\text{two-loop}) = 237^{+26}_{-24} \) MeV and \( \Lambda^{(5)}(\text{three-loop}) = 219^{+25}_{-23} \) MeV are given in Ref. [1]. Then from the matching of \( \alpha_s(\mu) \) at the scale \( \mu = \bar{m}_b \) (\( \bar{m}_b \) is the running mass in the MS scheme) and taking \( \bar{m}_b = 4.3 \pm 0.2 \) GeV [1] one can find \( \Lambda^{(4)}(\text{three-loop}) = 296^{+31}_{-29} \) MeV or in the two-loop approximation \( \Lambda^{(4)} \) is

\[
\Lambda^{(4)}(\text{two-loop}) = 338^{+33}_{-31} \text{ MeV}. \tag{34}
\]

It is of interest to compare \( \alpha_s(\mu) \) for \( \Lambda^{(4)} \) given by Eq. (34) with the fitted values \( \tilde{\alpha}_s(\mu) \) used in different theoretical analyses: \( \tilde{\alpha}_s(3.25) = 0.251 \pm 0.009 \) whereas in Ref. [4] the fitted value \( \bar{\alpha}_s(3.25) = 0.33 \); \( \alpha_s(4.60) = 0.221 \pm 0.007 \) while in Ref. [5] \( \bar{\alpha}_s(4.6) = 0.27 \). In both the fitted values appeared to be about 20\% larger.

This 20\% difference implies either very large values of \( \Lambda^{(4)} \) or an significantly smaller scale of \( \mu \). For example, \( \alpha_s(\mu_0) = 0.33 \) with the conventional \( \Lambda^{(4)} \), Eq. (34), corresponds to \( \mu_0 = 1.80 \pm 0.18 \) GeV instead of \( \mu = 3.25 \) GeV in Ref. [4] and this \( \mu_0 \) would be in good agreement with the one cited in Refs. [6,7] and with our result (see Sec. IX).

In our present analysis when different sets of parameters are taken, we shall impose two additional restrictions

(1) For the given \( P \)-state the extracted value of \( \tilde{\alpha}_s(\mu) \) must be the same for the tensor and the spin-orbit splittings, because both interactions have the same \( r^{-3} \) behavior and they also have the same characteristic size (momentum).

(2) Only those sets of parameters for which the fitted two-loop value of \( \tilde{\alpha}(\mu) \) corresponds to the conventional value of \( \Lambda^{(4)} \) in two-loop approximation, Eq. (34), are deemed appropriate.

VI. STATIC POTENTIAL

In heavy \( Q \bar{Q} \) systems the spin-dependent interaction contains the factor \( m^{-2} \) and therefore it is small and can be considered as a perturbation. For the unperturbed Hamiltonian we considered two cases, relativistic and nonrelativistic,

\[
H^R_0 = 2 \sqrt{p^2 + m^2} + V_{\text{sl}}(r) \tag{35}
\]

or

\[
H^{\text{NR}}_0 = \frac{\vec{p}^2}{m} + V_{\text{sl}}(r). \tag{36}
\]

Here the use of a static potential, \( V_{\text{sl}}(r) = V^P_{\text{sl}}(r) + V^N_{\text{sl}}(r) \), needs some remarks. The perturbative static potential is now known in two-loop approximation [28], but for our discussion it is enough to take it in one-loop approximation from [3]

\[
V^P_{\text{sl}} = \frac{4}{3} \alpha_v(r) \frac{\alpha_s(\mu)}{r}. \tag{37}
\]

Here the vector coupling constant \( \alpha_v(r) \) is expressed through \( \alpha_s(\mu) \) in the MS scheme in the following way [3]:

\[
\alpha_v(r) = \alpha_s(\mu) \left[ 1 + \frac{\alpha_s(\mu)}{\pi} \left( \frac{1}{a_1} + \frac{\beta_0}{2} \left[ \ln(\mu r) + \gamma_E \right] \right) \right] \tag{38}
\]

\[
\frac{4}{\beta_0} \frac{\alpha_s(\mu)}{\ln[(\Lambda_R r)^{-2}]}.
\]

In Eq. (38) we have used \( \alpha_s(\mu) = 4 \pi/[\beta_0 \ln(\mu^2/\Lambda^{(4)}_{\text{MS}})] \), and the conventional QCD constant in coordinate space: \( \Lambda_R = \Lambda^{(4)}_{\text{MS}} \exp(\gamma_E + a) \) where \( a = 2 a_1 / \beta_0 \). We see that the dependence on \( \mu \) disappears. The constants are: \( \beta_0 = 11 - 2 n_f / 3 \), so for \( n_f = 4 \), \( \beta_0 = 25 / 3 \); \( a = 31 / 12 - 5 n_f / 18 \), so for \( n_f = 4 \), \( a = 53 / 36 \).

This expression is valid only for small radiative corrections or small distances: \( r e^{-2} \bar{\Lambda}^{(4)}_{\text{MS}} \ll 1 \) or \( r e^{-2} \text{ GeV}^{-1} = 0.4 \) fm (\( \bar{\Lambda}^{(4)}_{\text{MS}} \approx 0.3 \) GeV). However, in bottomonium the sizes of the different states are varying in a wide range, e.g., typical values of the root-mean-square radius \( R(nL) = \sqrt{(r^2)_{nL}} \), are

\[
\begin{align*}
R(1S) & = 0.2 \text{ fm}, \quad R(1P) = 0.4 \text{ fm}, \\
R(2S) & = 0.5 \text{ fm}, \quad R(2P) = 0.65 \text{ fm}, \\
R(3S) & = 0.7 \text{ fm}, \quad R(3P) = 0.85 \text{ fm}, \quad R(4S) = 0.9 \text{ fm}.
\end{align*}
\tag{39}
\]
These numbers are practically independent of the choice of the static potential parameters and the confining potential, provided the chosen potential reproduces the bottomonium spectrum with good accuracy.

From Eq. (39) one can see that the sizes of the $nL$ states run from 0.2 to 0.9 fm. Therefore the perturbative potential, Eq. (38), valid for $r \ll 0.4$ fm, can be used only for low-lying states. For the 1S, 2S, and 1P states this perturbative interaction (also with two-loop corrections) was analyzed in detail in Refs. [6,7] and there it was found that (i) for the 1S and 2S states the values of $\mu$ are different and (ii) $\mu$ is smaller in the 2S state. Therefore, one can expect that for every level a specific consideration is needed to determine $\mu$ or $\alpha_s(\mu)$.

To describe the $2P$ state, the size of which is about 0.65 fm, or the $b\bar{b}$ spectrum as a whole, a different approach is needed. Here we suggest instead of the perturbative potential Eq. (37) to use the perturbative potential in background vacuum field, $V_B(r)$:

$$V_B(r) = -\frac{4}{3} \frac{\alpha_p(r)}{r}.$$  (40)

in momentum space

$$V_B(q^2) = -\frac{4}{3} \frac{4\pi}{q^2} \bar{\alpha}_B(q^2), \quad q^2 = \vec{q}^2.$$  (41)

In this potential $\bar{\alpha}_B(q^2)$ is a vector coupling constant in vacuum background field which was introduced in Ref. [19] and applied to $e^+e^-$ hadrons processes in Ref. [21]:

$$\bar{\alpha}_B(q^2) = 4\pi \frac{\beta_0 t_B}{\beta_0^2 t_B(q)} \left[ 1 - \frac{\beta_1}{\beta_0} \ln t_B(q) \right], \quad t_B(q) = \ln \frac{q^2 + m_B^2}{\Lambda^2}.$$  (42)

with $\beta_0 = 25/3$. For the vector coupling constant, $\alpha_v(q^2), \Lambda$ differs from $\Lambda$ in the MS scheme: $\bar{\Lambda} = \Lambda^{(4)MS}_{(3)} \varepsilon^a = 481.47$ MeV, $a = 5/6 - 4/\beta_0 = 0.3533$, and $\Lambda^{(4)MS}_{(3)}$ was taken from Eq. (34). (In the MS scheme $\Lambda_B$ and $\Lambda_{MS}$ coincide for $n_f = 4.5$ because of their identical behavior at large $q^2$ [10].) The background mass $m_B$ was found from the fit to the charmonium fine structure in Ref. [10] where $m_B = 1.1$ GeV was obtained.

In coordinate space $\alpha_p(r)$ can be calculated from the Fourier transform of the potential Eq. (41) with $\bar{\alpha}_B(q^2)$ given by Eq. (42). Then

$$\alpha_p(r) = \frac{8}{\beta_0} \int_0^\infty dq \frac{\sin qr}{q t_B(q)} \left[ 1 - \frac{\beta_1}{\beta_0} \frac{\ln t_B(q)}{t_B(q)} \right].$$  (43)

The strong coupling constant in vacuum background field maintains the property of asymptotic freedom at small $r, r \ll \Lambda^{-1}$ and $r \ll m_B^{-1}$,

$$\alpha_p(r \to 0) = -\frac{2\pi}{\beta_0 \ln(\Lambda e^r)}.$$  (44)

Here the function $\gamma = \gamma(r)$ is

$$\gamma = \gamma(r) = \gamma_E + \Sigma, \quad \Sigma = \sum_{k=1}^{\infty} \frac{(-m_B r)^k}{k!},$$  (45)

or at small $r$

$$\gamma = \gamma_E - m_B r,$$  (46)

whereas in standard perturbative theory $\gamma_p = \gamma_E = 0.5772$. Due to the dependence on the distance $r$ in Eq. (46) the expression Eq. (44) is always bounded.

For large $r^2$, $r^2 \gg m_B^{-2}$, the limit of $\alpha_p(r)$ in Eq. (43) tends to a constant, denoted as $\alpha_B(\infty)$ and called the freezing value

$$\alpha_B(\infty) = \frac{4\pi}{\beta_0 t_B} \left[ 1 - \frac{\beta_1}{\beta_0} \ln t_B(q) \right], \quad t_B = \ln \frac{m_B^2}{\Lambda^2}.$$  (47)

From the integral Eq. (43) it can be shown that the freezing value is the same in coordinate and in momentum space, $\alpha_B(r \to \infty) = \alpha_B(q^2 = 0)$. The properties of $\alpha_B(r)$ were discussed in Refs. [10,18,19] and a detailed analysis of $\alpha_B(r)$ will be published elsewhere. In the intermediate region, $0.2 \text{ fm} < r < 0.9 \text{ fm}$, $\alpha_B(r)$ approaches rapidly the value $\alpha_B(\infty)$.

Therefore, to study the bottomonium spectrum as a whole it is convenient to introduce an effective constant $\alpha_{\text{eff}}$:

$$\alpha_{\text{eff}}(r) = \alpha_{\text{eff}} + \alpha_{\text{eff}}^2(r), \quad \alpha_{\text{eff}} = \text{const}, \quad |\delta \alpha_{\text{eff}}(r)| \ll \alpha_{\text{eff}},$$  (48)

and to consider the contribution from the term $\delta V_B(r)$,

$$\delta V_B(r) = -\frac{4}{3} \frac{\delta \alpha_B(r)}{r},$$  (49)

as a perturbation. Then in the Hamiltonian (22) the static interaction

$$V_0(r) = -\frac{4}{3} \frac{\alpha_{\text{eff}}}{r} + \sigma r + C_0$$  (50)

will be taken into account as an unperturbed interaction.

For the nonperturbative interaction a linear form $\sigma r$ will be taken and therefore the static potential in the unperturbed Hamiltonian $V_0(r)$,

$$V_0(r) = -\frac{4}{3} \frac{\alpha_{\text{eff}}}{r} + \sigma r + C_0$$  (51)

coincides with the well known Cornell potential. Later, the values of the string tension $\sigma$ will be varied in the range 0.17–0.20 GeV$^2$. We shall present a detailed analysis of the $b\bar{b}$ spectrum in a separate paper.

**VII. RELATIVISTIC CORRECTIONS**

There exists the point of view that in bottomonium the relativistic corrections are small because of the heavy $b$ quark mass. Indeed, the comparison of levels and mass differences for the Schrödinger equation and the Salpeter equation, Eqs. (35),(36), in general, confirms this statement (here
The static potential is supposed to be the same in both cases. In Table I the $b\bar{b}$ mass differences are given for two typical sets of parameters. From Table I one can see the following.

(i) Relativistic corrections are small for large mass differences like $M(n_{L}) - M(n-1_{L})$ or $M(n_{L}) - M(n_{L}-1)$.

(ii) For close lying levels, like $\Delta_1 = M(2S) - M(1P)$ and $\Delta_3 = M(3S) - M(2P)$, the corrections are essential, about 15%, and to get $\Delta_1$ and $\Delta_3$ close to the experimental data it is necessary to take into account the contribution from the perturbation $\delta V_{B}(r)$ Eq. (49). In the relativistic case the influence of the phenomenon of asymptotic freedom appears to be more essential than in the nonrelativistic (NR) case.

The relativistic corrections are becoming essential for some matrix elements, which determine the fine structure splittings (see Table II). To calculate them in the relativistic case (for the Salpeter equation) the expansion of the wave function in a series over Coulomb-type functions was used as it was suggested in [29]. The numbers obtained have a computational error $\lesssim 10^{-4}$ (the dimension of the matrixes D was varied from D=20 to D=40).

From the numbers given in Tables II and III one can conclude that for $1P$ and $2P$ states the root-mean-square radii practically coincide in the relativistic and the NR cases, for the matrix element $\langle r^{-1} \rangle$ the difference between both cases is small, about 3% for the $1P$ state and about 5% for the $2P$ state; in the relativistic case $\langle r^{-1} \rangle$ and therefore $|\alpha_{NP}(nP)|$ is slightly larger, in the relativistic case the values of $\langle r^{-3}\ln mr \rangle$ are about 7% (10%) larger for the $1P(2P)$ state for given set of chosen parameters, for the Salpeter equation the matrix element $\langle r^{-3} \rangle$ is larger by about 14% (22%) for the $1P(2P)$ state, and the largest relativistic correction was found for the factor $f_{d}$ given in Eq. (6). This difference is about 30% for the $1P$ state and 36% for the $2P$ state. The numbers given do practically not change for different sets of parameters. So our averaged value of $f_{d}(nP)$ ($\alpha_{NP} \approx 0.35$) are

\[ f_{d}(1P) = 0.085 \pm 0.010 \text{ GeV}^{2}, \]
\[ f_{d}(2P) = 0.106 \pm 0.008 \text{ GeV}^{2}. \]  

The theoretical error in Eq. (52) ($\approx 10\%$) mostly comes from the variation of the $b$ quark mass (in the range 4.6–5.0 GeV).

The increasing of $f_{d}(nP)$ in the relativistic case directly affects the values of $\alpha_{s}(\mu)$ extracted from the fine structure data because according to Eq. (32)

\[ \alpha_{s}(\mu) = \sqrt{\frac{\pi m\Delta(nP)}{2f_{d}(nP)}}. \]

\[ \Delta(nP) = \eta_{exp}(nP) - |\alpha_{NP}(nP)|, \]

(53)

is proportional to $f_{d}^{-1/2}$ and $\alpha_{s}(\mu)$ is about 15% smaller in the relativistic case. This result obtains both for $1P$ and $2P$ states.

Therefore, below we shall use only matrix elements calculated for the Salpeter equation, in this way taking into account the relativistic corrections. A last remark concerns the choice of the quark pole mass, $m_{\text{pole}} = m$ which enters the Salpeter equation [6]. Here we study the spin structure of the $\chi_{b}$ mesons determined by the spin-dependent potentials now known only in one-loop approximation. Therefore the pole mass of the $b$ quark will be taken also in one-loop approximation [30]:

\[ m = m_{\text{pole}} = m_{F}(m_{b}^{2})\left(1 + \frac{4}{3} \frac{\alpha_{s}(m_{b}^{2})}{\pi}\right). \]

*For the parameters see Table I.

In Eq. (54) $\tilde{m}(m^2)$ is a running quark mass in the $\overline{MS}$ renormalization scheme, its value from Ref. [1] is $\tilde{m} = 4.3 \pm 0.2$ GeV. Then taking $\Lambda^{(4)}$ from Eq. (34) one finds $m$ in the range

$$4.5 \text{ GeV} \leq m \leq 5.0 \text{ GeV}. \quad (55)$$

Only values of the mass in this range will be used later in our calculations.

VIII. $\alpha_v(\mu)$ FOR THE 2P STATE

For the 2P state $\alpha_v(\mu)$ can be immediately found from the relation (32) for the chosen static potential with fixed parameters $\alpha_{eff}, \sigma,$ and $m$. At first, we shall give an estimate of $\alpha_v(\mu)$ using the following results.

1. The nonperturbative spin-orbit splitting $|a_{NP}(2P)|$ depends weakly on the choice of the parameters, provided the $b\bar{b}$ spectrum is described with good accuracy

$$|a_{NP}(2P)| = 1.95 \pm 0.15 \text{ MeV}. \quad (56)$$

2. In Eq. (30) the experimental error of $\eta_{exp}(2P)$ is not large and therefore the difference $\Delta(2P)$ Eq. (32) is known with an accuracy of about 20%:

$$\Delta(2P) = \eta_{exp}(2P) - |a_{NP}(2P)| = 2.40 \pm 0.04(\text{exp}) \pm 0.15(\text{th}) \text{ MeV}. \quad (57)$$

3. In our calculations the matrix element $f_4(2P)$ is changing in the narrow range

$$f_4(2P) = 0.106 \pm 0.008 \text{ GeV}^2. \quad (58)$$

Then, from the fitting condition (32) and the numbers given in Eqs. (56)–(58) the lower and upper bounds of $\tilde{\alpha}_v(\mu)$ can be determined:

$$\sqrt{m} - 0.37 < \tilde{\alpha}_v(\mu) < \sqrt{m} - 0.46. \quad (59)$$

Here a normalization mass, $m_0 = \frac{1}{2} M[Y(1S)] = 4.73$ GeV, was introduced for convenience. Here and below all numbers were calculated in the relativistic case, i.e., for the Salpeter equation.

From the estimates (59) it is clear that for the 2P state $\alpha_v(\mu) \approx 0.40$ turns out to be large for any set of the parameters of the static interaction. It is significantly larger than that obtained in Ref. [4] where $\alpha_v(3.25) = 0.33$ and in Ref. [5] where $\alpha_v(4.6) = 0.26$. In our calculations large values of $\tilde{\alpha}_v(\mu)$ are extracted irrespectively to the value of the scale $\mu$, which is still not fixed.

However, $\alpha_v(\mu)$ in Eq. (59) is varying in a rather wide range and its value is sensitive to small variations of the factors entering the condition (32). The value of $\alpha_v(\mu)$ is decreasing if the constant $\alpha_{eff}$ of the static interaction is growing. In our numerical calculations the value of $\alpha_{eff}$ is supposed to be in the range

$$0.35 < \alpha_{eff} < \alpha_B(q^2 = 0) \approx 0.48 \quad (60)$$

with a $b$ quark mass from the condition (55).

With the restriction (60) the fitted values of $\tilde{\alpha}_v(\mu)$ appeared to lie in the narrower range

$$\tilde{\alpha}_v(\mu) = 0.40 \pm 0.02(\text{th}) \pm 0.04(\text{exp}) \quad (b\bar{b}). \quad (61)$$

Here the experimental error comes from $\eta_{exp}$, Eq. (33), and the theoretical error is due to the variation of $\alpha_{eff}, m,$ and $\sigma$.

In the extracted value $\tilde{\alpha}_v(\mu)$, Eq. (61), the scale $\mu$ is still not specified. To find $\mu_2$ it is better to use the condition $c(2P) = c_{exp}$, Eq. (28), for the tensor splitting, because the theoretical uncertainty connected with the nonperturbative contribution to $c(2P)$ is negligible, $c_{NP} < 0.05$ MeV. This condition (28) turns out to be satisfied for the scale

$$\mu = \mu_2 = 1.02 \pm 0.02 \text{ GeV}, \quad (62)$$

which has a small theoretical error, 2%, while the extracted value of $\tilde{\alpha}_v(\mu)$, Eq. (61), was determined with an accuracy of 15%.

It is of interest to compare $\tilde{\alpha}(1.0) \approx 0.40$ with the value found in perturbation theory. The scale $\mu_2 \approx 1.0$ GeV is small, less than the running mass of the $c$ quark, $\tilde{m}_c = 1.3 \pm 0.2$ GeV [1], therefore $\tilde{\alpha}_v(1.0)$ should be calculated with $\Lambda = \Lambda^{(3)}$ (two-loop), $n_f = 3$. The value of $\Lambda^{(3)}$ can be found using the matching condition at $\mu = \tilde{m}_c$ and the value of $\Lambda^{(4)}$, Eq. (34). Then

$$\Lambda^{(3)}(\text{two-loop}) = 384^{+32}_{-30} \text{ MeV} \quad (63)$$

and correspondingly the two-loop strong coupling constant is

$$\alpha_v(1.0) = 0.53^{+0.06}_{-0.05} \quad (64)$$

which is 30% larger than our fitted value given by Eq. (61). It was suggested in Ref. [10] that this decreasing of $\tilde{\alpha}(\mu)$ at the scale $\mu_2 = 1$ GeV can be explained by the behavior of $\alpha_B(\mu)$ Eq. (42) in the vacuum background field, thus demonstrating the phenomenon of freezing of $\alpha_v(\mu)$. In Ref. [10], from a fit to the charmonium fine structure, the background mass $m_B$ in Eq. (42) was found to be (in the $\overline{MS}$ renormalization scheme)

$$m_B = 1.1 \text{ GeV}, \quad \Lambda^{(3)}_B(\text{two-loop}) = 400^{+40}_{-50} \text{ MeV} \quad (c\bar{c}). \quad (65)$$

Our extracted value of $\tilde{\alpha}(1.0)$ in Eq. (61) corresponds to the close value of $\Lambda^{(3)}_B$.

aFor the parameters see Table I.
bα_eff = 0.386, σ = 0.185 GeV², m = 5.0 GeV.

\[ \Lambda_0^{(3)}(\text{two-loop}) = 420^{+40}_{-30} \text{ MeV (b}\overline{b}) \] (66)

Note also that for the 1P state in charmonium the value
\[ \bar{\alpha}(1.0) = 0.38 ± 0.03(\text{th}) ± 0.04(\text{exp}) \] (67)

practically coincides with \( \bar{\alpha}(1.0) \) in bottomonium, 
\[ \bar{\alpha}(1.0) = 0.40 ± 0.02(\text{th}) ± 0.04(\text{exp}), \]
\[ \mu_2 = 1.02 ± 0.02 \text{ GeV} \] (68)

This coincidence is not, in our opinion, accidental: both states, the c\overline{c} 1P state and the b\overline{b} 2P state, have the same size: \( R = \sqrt{\langle r^2 \rangle_{bb}} = 0.62–0.65 \text{ fm} \). This coincidence of the values of \( \alpha_\circ(\mu) \) and of the sizes indicates that for the bound states the scale \( \mu \) is characterized by the size, but not the momentum, of the system. This result is in agreement with the predictions of Refs. [6,7].

With the use of the fitted values \( \bar{\alpha}_\circ(\mu_2) \), Eq. (68), the theoretical number obtained for the spin-orbit splitting \( a_{\text{tot}} \) automatically satisfies the third fitting condition Eq. (28). Calculated numbers of \( a \) and \( c \) are given in Table IV for three different sets of parameters. From these numbers one can see that the second order radiative corrections \( a_{P(2)} \) and \( c_{P(2)} \) are negative and rather large: about 25% for the tensor and 40% for the spin-orbit splittings.

Note that we have met here no difficulty to get a precise description of the tensor and spin-orbit splittings for the 2P state simultaneously, in contrast to the results of Ref. [5], where some difficulties have occurred, in our opinion, because of the choice \( \mu = m \) (see the discussion in Sec. V).

**IX. \( \alpha_\circ(\mu) \) FOR THE 1P STATE**

For the 1P state the scale-independent condition (32) cannot be used directly, because the important factor \( \Delta(1P) \) in Eq. (32) has a large experimental error. So in this case one needs to use the two \( \mu \)-dependent conditions, Eq. (28), on the splittings \( a \) and \( c \).

There exist a lot of variants where these two conditions can be satisfied. However, in many cases the two-loop values \( \bar{\alpha}_\circ(\mu_1) \) and \( \mu_1 \), extracted from those fits, correspond to a very large value of the QCD constant \( \Lambda^{(4)} \). Therefore, the additional requirement (21) that \( \Lambda^{(4)}(\text{two-loop}) \) should have a value in the range 307 MeV ≤ \( \Lambda(4) \) ≤ 371 MeV, is necessary. If this restriction is put, then in our calculations the extracted scale \( \mu_1 \) appears to lie in the narrow range
\[ \mu_1 = 1.80 ± 0.10 \text{ GeV} \] (69)

and
\[ \bar{\alpha}(\mu_1) = 0.33 ± 0.01(\text{exp}) ± 0.02(\text{th}) \] (70)

Our value for the scale \( \mu_1 \) turned out to be very close to that determined in Ref. [7], but our fitted value of \( \alpha_\circ(\mu_1) \) is about 15% larger than the one found in Ref. [7] where \( \bar{\alpha}_\circ(\text{three-loop}) = 0.29 \) and \( \Lambda^{(4)}(\text{three-loop}) = 230 \text{ MeV} \) [or \( \Lambda^{(4)}(\text{two-loop}) = 250^{+60}_{-60} \text{ MeV} \) is smaller than in our fit.

For the 1P state it was also observed that if a large value \( \sigma = 0.2 \text{ GeV}^2 \) is taken, then it is difficult to reach a consistent description of the tensor and the spin-orbit splittings simultaneously. Therefore here, as well as in the charmonium case [10], the values \( \sigma = 0.17–0.185 \text{ GeV}^2 \) are considered as preferable. Also the choice of a relatively large b quark mass,
\[ m_b = 4.75–4.9 \text{ GeV} \] (71)
gives rise to a better fit.

The results of our calculations for the 1P state are given in Table V from which one can see that the second order corrections \( c_{P(2)} \) and \( a_{P(2)} \) are relatively small, 8% and 1.5%, but still remain important for a fit to the experimental data. Also in all good fits the effective Coulomb constant \( \alpha_{\text{eff}} \) lies between \( \bar{\alpha}(\mu_1) \) and \( \bar{\alpha}_\circ(\mu_2) \):
\[ \bar{\alpha}(\mu_1) < \alpha_{\text{eff}} < \bar{\alpha}_\circ(\mu_2). \] (72)

In our analysis \( \mu_2(2P) \) is less than \( \mu_1(1P) \) and their ratio is almost inversely proportional to the ratio of the radii of these states
\[ \frac{\mu_1(1P)}{\mu_2(2P)} \approx 1.7–1.8; \quad \frac{\sqrt{\langle r^2 \rangle_{2P}}}{\sqrt{\langle r^2 \rangle_{1P}}} \approx 1.6–1.65. \] (73)

This result is in full agreement with the prediction of Refs. [6,7] about the decrease of the scale with increasing principal quantum number.
X. CONCLUSION

The precise experimental data on the masses of $\chi_b(1P)$ and $\chi_b(2P)$ give a unique opportunity to determine the QCD strong coupling constant at low-energy scales. In our analysis of fine structure splittings we found the following.

1. The relativistic corrections which are small for such characteristics as the $b\bar{b}$ levels, radii, and matrix element $<r^{-1}>$, are nevertheless essential for the determination of the factor $f_q(nP)$, which is inversely proportional to the extracted value of $\alpha_s^\pi(\mu)$.

2. From a $\mu$-independent analysis of the $2P$ state, the value $\bar{\alpha}_s(\mu_2)\approx0.40$ was extracted. The scale $\mu_2=1.0\pm0.02$ GeV, determined from the tensor splitting, appears to be practically unchanged for any chosen set of parameters.

3. The extracted value $\alpha(1.0)\approx0.40$ is about 30% lower than the one found in perturbation theory if $\Lambda^{(3)}=384^{+32}_{-30}$ MeV was used. This value agrees with the fitted $\alpha_s(1.0,\tilde{c}\bar{c})$ extracted from the analysis of the charmonium fine structure. This result can be naturally explained in the framework of background perturbation theory and is compatible with the freezing of the coupling constant.

4. The scale $\mu_1\approx1.8$ GeV for the $1P$ $b\bar{b}$ state obtained here agrees with the prediction in Ref. [7] but corresponds to the larger value $\Lambda^{(2)}(two-loop)=338^{+35}_{-31}$ MeV, which gives rise to $\alpha_s(M_Z)=0.119\pm0.002$.

5. The preferred values of the pole mass of the $b$ quark are found to be $m_b=4.7-4.9$ GeV but from the fine structure analysis we could not narrow their range.

Our results have confirmed the important observation of Yndurain et al. [6,7] that the strong coupling constant is increasing for states with a larger size or larger principal quantum number and this fact is essential in many aspects of quarkonium physics.
