A systematic review of Instrumental Activities of Daily Living scales in dementia: room for improvement

S A M Sikkes,¹ ² E S M de Lange-de Klerk,¹ Y A L Pijnenburg,² ³ P Scheltens,² ³ B M J Uitdehaag¹ ³

ABSTRACT

Background: Instrumental Activities of Daily Living (IADL) questionnaires can be helpful in diagnosing dementia and are often used for clinical follow-up and treatment evaluation in dementia patients. Despite the large number of questionnaires, their quality has received little attention.

Objective: To systematically review the measurement properties of all available structured informant-based (I)ADL questionnaires, developed or validated for use in demented patients.

Methods: A systematic literature search was conducted in MEDLINE, PsycINFO and EMBASE for psychometric articles on (I)ADL questionnaires. In addition, reference lists of all retrieved articles were screened. Standardised criteria were used to assess the quality of the measurement properties. When possible, investigators were contacted to obtain missing information. Two authors independently extracted studies and performed the quality assessment of the questionnaires.

Findings: Thirty-two articles were selected, covering 12 (I)ADL questionnaires. Information on 52.3% of the quality aspects was not available, 32.4% of the ratings were indeterminate, 8.1% were positive, and 7.2% were negative. Out of eight measurement properties, two scales (the DAD and the Bristol ADL) received two positive ratings and were classified as of moderate quality. Five scales (ADL-PI, ADL-IS, B-ADL, CSADL and Lawton IADL) received one positive rating.

Interpretation: The findings indicate that improvements in and more data on psychometric properties of (I)ADL questionnaires for dementia patients are necessary in order to justify their use.

Additional data (appendix) are published online only at http://jnp.bmj.com/content/vol80/issue1

Received 13 June 2008
Revised 16 September 2008
Accepted 22 September 2008

Functional decline is an essential feature of all dementias and is therefore embedded in the diagnostic criteria for dementia.¹ This decline is commonly assessed using “functional ability” or “activities of daily living” measurement instruments. Activities of daily living can be divided into Basic Activities of Daily Living (BADL) and Instrumental Activities of Daily Living (IADL). BADL are self-maintenance skills such as bathing, dressing and toileting. IADL involve more complex activities, such as preparing a meal, handling finances and shopping.² These instrumental activities generally require a greater complexity of neuropsychological organisation and are in consequence more likely to be vulnerable to the early effects of cognitive decline.³ ⁴ Measuring IADL can therefore be helpful in diagnosing early dementia.⁵ ¹⁰ Since IADL also gives an indication of patient dependency, it is frequently used for clinical follow-up and to evaluate treatments.⁶ ⁷ ¹¹

Methods to assess IADL comprise self-reported questionnaires, performance-based assessment and informant-based questionnaires. Self-reported questionnaires are difficult to assess in dementia patients, since disease insight is frequently impaired.¹² ¹³ Observation or direct assessment has the advantage of directly obtaining information without relying on self- or informant report. Nonetheless, a major drawback of this method is the time-consuming aspect of these instruments, with assessment times up to 1.5 h.⁶ ¹⁰ Hence, the most common method is the use of informant-based questionnaires.

A large number of these (I)ADL informant-based questionnaires are available, and their number is still growing.⁵ ¹³ Despite the widespread use of these questionnaires, little attention has been paid to their quality. For example, in the light of an early diagnosis of dementia, it still remains unclear which of the existing IADL questionnaires might identify people at risk for dementia.⁷

A critical review of IADL questionnaires is therefore timely and needed in view of the expected increase in clinical trials in early Alzheimer disease (AD). Here, we provide an overview of all available structured informant-based IADL questionnaires, developed or validated for the use in AD. Additionally, we set out to evaluate the psychometric properties of these questionnaires. Our final aim was to identify questionnaires useful in the identification of early dementia, particularly in young patients.

METHODS

Data sources

Computer-based literature searches were performed in the PubMed (1950–2007), PsycINFO (1887–2007) and Embase (1966–2007) databases, concluding in November 2007. These databases were searched with the search terms Activities of daily living (MeSH), dementia, Alzheimer, rehabilitation, ADL, functional ability, everyday functioning and instrumental ADL, complex ADL, advanced ADL, functional ability, everyday functioning and activities of daily living. An additional search was conducted with the terms ADL (MeSH) and dementia (MeSH), to ensure no questionnaires were missed. No limits were set in languages. Case reports and clinical trials were excluded. Two authors (EdL-dK and SS) independently screened abstracts and titles to identify those articles.
relevant to the research question. In addition to the computerised databases, a book with an overview of assessment scales in old age psychiatry was hand-searched. Reference lists of all articles related to the research question were screened, and potentially relevant articles were subsequently retrieved and assessed.

**Data extraction and data synthesis**

Questionnaires aimed at measuring (I)ADL, complex ADL, advanced ADL, functional ability, functional disability or everyday functioning were selected. When the primary measurement aim was otherwise, for example quality of life or general deterioration, the questionnaire was excluded. The questionnaire had to be disease-specific, that is developed or validated for use in dementia patients. In addition, the questionnaire had to be structured and informant-based. In consequence, self-report or clinical judgement scales without operationally defined anchor points were excluded. Furthermore, the questionnaire had to be developed or validated for use in Western society (Europe or Northern America).

A study was selected when its primary objective was the development or the clinimetric evaluation of an (I)ADL questionnaire. We aimed to identify the original validation article and all subsequent psychometric articles. Studies addressing other objectives, such as treatment evaluation, were excluded to avoid circular reasoning.

All questionnaires meeting the inclusion and exclusion criteria outlined above were incorporated in the review. They were reviewed on relevant psychometric characteristics according to the “quality criteria for measurement properties of health status questionnaires” developed by Terwee et al. Authors were contacted if further information, such as additional unpublished data, was required.

**Quality assessment of the questionnaires**

The quality of the questionnaires was evaluated on the following eight measurement properties: (1) content validity, (2) internal consistency, (3) criterion validity, (4) construct validity, (5) reproducibility, (6) responsiveness, (7) floor- and ceiling effects and (8) interpretability. Each aspect was rated as positive, negative or indeterminate, depending on the design, methods and outcomes of the studies. The quality and rating criteria are outlined in the appendix (I).

In general, a positive rating was given when the study was adequately designed, executed and analysed, had adequate sample sizes and had satisfying results. An indeterminate rating was given when there was an inadequate (description of) design and execution, inadequate methods or analyses, the sample size was too small, or there were methodological shortcomings. A negative rating was given when unsatisfactory results were found despite adequate design, execution, methods, analyses and sample size. When information about the relating criteria was lacking, a “no information available” rating was given.

Two authors (ESmDL-DK and SAMS) independently rated the questionnaires, and discrepancies were resolved by consensus. Where consensus could not be reached, a third reviewer was consulted.

**Content validity**

The content validity refers to the way in which items of the questionnaire cover the domain(s) under investigation. In order to be able to judge the content validity of a questionnaire, authors should provide information regarding the measurement aim of the questionnaire, the target population, the concepts the questionnaire intends to measure, the process of item selection and the interpretability of the items. The items of the questionnaire should contain relevant items, and to ensure its relevance, the target population should have been involved in the process of item selection to obtain a positive rating on this property.

**Internal consistency**

Internal consistency concerns the extent to which items in a (sub)scale are correlated, and are as such measuring the same concept. In order to evaluate the internal consistency, authors should have performed a factor analysis to check for subscales in the questionnaire. When subscales are found, the internal consistency should have been tested separately for these subscales. Internal consistency can be determined by calculating the Cronbach alpha. A positive rating for this property was obtained when the Cronbach alpha was between 0.70 and 0.95.

**Criterion validity**

Criterion validity refers to the extent to which scores on a scale relate to another measure of the construct under study, ideally a “gold standard.” A positive rating is given if the correlation with the gold standard is at least 0.70.

**Construct validity**

When no absolute “gold standard” is available, the validity must be investigated by means of indirect evidence, such as establishing the construct validity. A construct is some postulated attribute of people, assumed to be reflected in test performance. To investigate construct validity, the scores on the questionnaire under study are correlated with scores on other measurement instruments which are known to be related (or not) to the construct under study. Authors should provide hypotheses about the relation between the construct under study and the other constructs in advance, and at least 75% of the results should be in correspondence with the hypotheses to receive a positive rating.

**Reproducibility**

Reproducibility concerns the degree to which repeated measurements in stable patients provide the same results. The concept of reproducibility embraces two aspects, namely agreement and reliability. Reliability addresses whether patients can be distinguished from each other, despite measurement error. This can be determined by calculating a reliability parameter, generally an Intraclass Correlation Coefficient (ICC). The ICC for agreement, which reflects both systematic and random differences in test scores, is preferred. A positive rating is given when theICC is at least 0.70. The second aspect, agreement, reflects the extent to which repeated measurements give the same results. This can be expressed as the standard error of measurement (SEM) or with the limits of agreement of Bland and Altman. In case of high agreement, the measurement error is small. The SEM can be converted into the smallest detectable change (SDC), which is the smallest within-person change, above measurement error. A positive rating is given when the SDC or the limits of agreement are smaller than the minimal important change (MIC). The MIC is the smallest difference in score in the domain of interest which patients perceive as beneficial and would mandate, in the absence of troublesome side effects and excessive costs.
Responsiveness
Responsiveness is the ability of a questionnaire to detect a meaningful or clinically important change over time in a clinical state. To detect such a change, the questionnaire should be able to distinguish clinically important change from measurement error. Responsiveness is determined by calculating Guyatt's responsiveness ratio (RR) or the area under the receiver operating characteristics (ROC) curve (AUC). The latter is a measure of the ability to distinguish patients who have and have not changed, according to an external criterion. A positive rating was given when the RR was at least 1.96 or the AUC was at least 0.70.

Floor- and ceiling effects
Floor- or ceiling effects are present if more than 15% of the patients obtain the lowest or highest possible score. In consequence, patients in these upper or lower ends cannot be distinguished from each other, and change cannot be measured. A positive rating was given when these effects were absent.

Interpretability
Lastly, the interpretability of the questionnaire is rated. This is the extent to which one can assign qualitative meaning to quantitative scores. One can interpret scores on a questionnaire when information is present concerning what score or change in score is clinically meaningful. Authors received a positive rating when they provided scores of a reference population and relevant subgroups of patients, and when a MIC was defined to enable interpretation of change scores over time.

RESULTS
The initial Medline search produced 2104 possible sources referring to (I)ADL in combination with dementia. All abstracts and titles were screened using the inclusion/exclusion criteria. Twenty-three articles relevant to the research question were identified, covering 13 questionnaires. The additional searches in PsycINFO and Embase disclosed one other relevant article. Cross-referencing led to the identification of another six articles. Resources were unavailable to translate two possibly relevant articles (Spanish and French, concerning the Lawton & Brody IADL questionnaire). One questionnaire (the Daily Activities Questionnaire) was excluded because it was developed with item response techniques (instead of classical test theory), and the quality criteria were not suitable for these techniques.

For further investigation, 28 articles covering 12 questionnaires were selected. Table 1 provides the full names and abbreviations of the questionnaires.

Description of questionnaires
Table 2 presents an overview of the included questionnaires. The ADCS-ADL, ADCS-ADL-sev, ADL-IS, ADLQ, B-ADL, Blessed DS, Bristol ADL, CSADL, DAD, IDDD and IIDDD were disease-specific scales for dementia patients. The ADLQ, B-ADL, DAD and IDDD were aimed at patients in later stages of dementia. The ADCS-ADL-sev was aimed at patients in later stages of dementia. The ADL-PI was aimed at healthy older people in prevention trials for AD. The Lawton IADL was a generic scale, developed for community-resident older people. This questionnaire did not meet the inclusion criteria, but was included by exception, because it is currently the most widely applied IADL questionnaire for dementia patients.

Most questionnaires combined Instrumental ADL with Basic ADL, behaviour, cognition or social functioning. The Lawton IADL and the ADL-PI were the only scales designed to measure exclusively IADL.

The measurement aims of the questionnaires were to assess ADL (ADCS-ADL-sev, Blessed DS, CSADL, DAD, IDDD, Lawton IADL), to detect changes in ADL (ADL-PI, ADL-IS, ADLQ, B-ADL) or both (ADCS-ADL, Bristol ADL). No questionnaires were aimed at the early identification of dementia in younger patients.

Content validity
In the development of most questionnaires, suggestions from experts, investigators or the target population were incorporated. In some validation articles, no information about how the generation and selection of the items took place was found, such as in the Blessed DS, IDDD and the Lawton IADL articles. For the ADLQ, no information about the target population involvement was provided. Target population was involved in the item selection of the Bristol ADL, ADL-IS, DAD and CSADL. For all these questionnaires except the Bristol ADL, there was also involvement of experts or investigators. No target population was involved in the selection of items for the B-ADL, item selection was performed by experts only.

Internal consistency
A Cronbach alpha was reported for the B-ADL, CSADL, DAD, IDDD and Lawton IADL, ranging from 0.78 to 0.98. The only studies in which factor analysis was performed prior to the computation of the Cronbach alpha were studies of the Lawton IADL and the B-ADL scale. For the B-ADL, the Cronbach alpha was 0.98; for the Lawton IADL, two subscales were found, with a Cronbach alpha of 0.91 and 0.78.

Criterion validity
Since there is no apparent “gold standard” available for ADL, most studies did not provide information about criterion validity. For the Blessed DS, however, the authors suggested the senile plaque count in the brains of (diseased) patients as a gold standard. The correlation with this standard for demented patients was 0.40.

Construct validity
In most studies, other instruments in addition to the (I)ADL questionnaire were administered, most frequently the MMSE. For the ADLQ, hypotheses were presented relating to an instrument measuring both ADL and behaviour. It was expected that the correlation with ADLQ would be higher for the ADL section than for the behaviour section. These hypotheses were confirmed, with a correlation of 0.71 with the ADL section and a correlation of 0.46 for the behaviour section. For the Bristol ADL, hypotheses were also formed in advance, which was explained in a personal communication by Dr Romola S. Bucks (email, 14 May 2008). Hypotheses relating to the magnitude and direction of expected relationships with other instruments were not presented for any other questionnaires.

Reproducibility
Agreement
Information about agreement was only presented for the Blessed DS. The limits of agreement were presented, but an
MIC was not defined. Information regarding agreement was not present for any of the other questionnaires.

Reliability
Reliability was investigated for nine questionnaires. Kappas were computed for the ADLQ and Bristol ADL. Spearman rank-order correlations were presented for the CSADL and B-ADL (personal communication with Dr Hartmut Lehfeld, email, 8 April 2008). Pearson correlations were presented for the ADL-PI. ICCs were computed for the Blessed DS, DAD, DAQ, IDDD and Lawton IADL, with values ranging from 0.30 to 0.94. The sample sizes for the Lawton IADL were too small (<50 patients). For the DAD and the Blessed DS, an ICC was obtained with an adequate sample size (ICC = 0.95 and ICC = 0.30).

Responsiveness
Change over time was addressed in studies of the DAD, ADLQ, ADL-PI, Lawton IADL, Bristol ADL and ADCS-ADL-sev. These studies presented change scores over time only. Several studies also compared change scores with scores on other related measurement instruments. No MIC was defined for any of the questionnaires.

Floor or ceiling effect
Floor or ceiling effects were reported for the CSADL (78% obtained the lowest score) and the Lawton IADL (approximately 20% obtained the highest score). No floor or ceiling effects were present for the B-ADL, as was explained in a personal communication with Dr Hartmut Lehfeld (email, 8 April 2008). No or unclear information about possible floor or ceiling effects was provided for the remaining questionnaires.

Interpretability
For eight questionnaires, information on different relevant subgroups was available. These subgroups included groups of different dementia severity, healthy older people, physically impaired, MCI, depression or different age groups. The mean and SD scores were presented in most articles.

Overall quality
Table 3 shows the overall quality assessment of the 12 (I)ADL questionnaires, summarising each property as good (+), doubtful (?), poor (−) or no information found (NA) according to the criteria of Terwee et al.19 Information on 52.3% of the quality aspects was not available, 8.1% of the ratings were positive,
32.4% of the ratings were indeterminate, and 7.2% were negative. The ADL-PI, ADL-IS, B-ADL, CSADL and Lawton IADL received one positive rating, and the DAD and Bristol ADL received two positive ratings.

**DISCUSSION**

We identified 12 questionnaires for the evaluation of (I)ADL in dementia. None of these questionnaires provided information for all measurement properties. Of the ratings, 81.1% were positive, 7.2% were negative, and 32.4% were indeterminate, often due to inadequate data analyses or sample sizes. Overall, the DAD and the Bristol ADL received the best ratings for their clinimetric properties. Although several questionnaires were aimed at early dementia, no diagnostic questionnaire specific for use in young patients was found.

To our knowledge, no previous study has systematically addressed the psychometric properties of IADL questionnaires for dementia patients using well-defined criteria. Previous reviews described only the content of the scales or a limited number of psychometric properties, without evaluating those using clear criteria. In our study, the DAD and the Bristol ADL received the best ratings, but when considering all eight quality aspects, these questionnaires are only of moderate quality. The rating of the questionnaires was complicated by the lack of psychometric information. When possible, authors were contacted to obtain missing information. Several authors provided additional information, but a large percentage of measurement properties remained unknown or unclear. It was therefore impossible to give a judgement on several important quality criteria such as responsiveness, reproducibility, construct validity and interpretability.

The quality criteria used in this article might be considered rather strict, since no questionnaire received satisfactory ratings on all criteria. For example, an important aspect for several psychometric properties was the definition of a minimal important change. Since no minimal important change (MIC) was defined for any of the questionnaires, it was therefore impossible to receive a positive rating on agreement, responsiveness and interpretability. Defining a MIC is one of the most important aspects of an evaluative questionnaire. Since half of the questionnaires are aimed at the evaluation of ADL and measuring change, one would expect more attention for this aspect, especially in view of the use of these scales in clinical trials and the relative weight put on IADL measures as outcome variable by registration authorities. Another example of the strictness of the criteria is the negative rating the B-ADL received for internal consistency. The Cronbach alpha for this questionnaire was too high according to the quality criteria. A very high Cronbach alpha is indicative of redundancy of items, but it does not necessarily mean that the internal consistency is not good. Therefore, this negative rating is more indicative of redundant items, and the questionnaire could possibly consist of fewer items. We choose these quality criteria because they are the most specific criteria currently available. These criteria clearly pointed out flaws in the existent IADL questionnaires. The methods used are often inadequate, and psychometric information is lacking. These findings are in concordance with previous reviews, in which serious limitations of ADL measurement instruments were mentioned.

Making recommendations about the use of IADL questionnaires is extremely difficult because of a lack of information. When choosing a questionnaire, it is important to bear in mind that a “good” score for many measurement properties is a start, but in itself not enough. Which questionnaire is best depends on the measurement aims. In general, one may say that responsiveness analyses are of particular importance for evaluative questionnaires. For diagnostic questionnaires, a good reproducibility is important, in order to distinguish individuals from each other. The applicability of the questionnaire, an aspect that has not received attention in this review, can also be of importance in choosing an appropriate questionnaire.

Even though this review indicated several serious limitations in currently available IADL questionnaires, further investigations could result in better psychometric properties. Validation is an ongoing process and can therefore improve over time when new studies are conducted. Questionnaires with a positive rating on content validity (ADL-PI, ADL-IS, Bristol ADL, CSADL and DAD) provided an appropriate justification for the items included in the questionnaire. The DAD also received a positive rating on reliability and is therefore of particular interest for further study. Our findings indicate that improvements in psychometric properties of these questionnaires are needed in order to justify their use in clinical practice and for research purposes.
