MINIX: A UNIX CLONE WITH SOURCE CODE

ABSTRACT

MINIX is a complete rewrite of UNIX.† Neither the kernel nor the utility programs contains any AT&T code, so the source code is free of the AT&T licensing restrictions and may be studied by individuals or in a course. The system runs on the IBM PC, XT, or AT, and does not require a hard disk, thus making it possible for individuals to acquire a UNIX-like system for home use at a very low cost.

Internally, MINIX is structured completely differently from UNIX. It is a message passing system on top of which are memory and file servers. User processes can send messages to these servers to have system calls carried out. The paper describes the motivation and intended use of the system, what the distribution contains, and discusses the system architecture in some detail.

1. INTRODUCTION

When AT&T first licensed UNIX outside of Bell Laboratories, it was widely studied in operating systems courses at universities (and in industry). Prof. John Lions of the University of New South Wales in Australia even wrote a little booklet providing a commentary on the source code, which for the most part was comment-free. Lions' booklet plus the UNIX source code made it possible for students to get hands-on experience working with, and modifying the code of a real operating system.

With the advent of Version 7, AT&T decided to put an end to the teaching of UNIX to students, and added a clause to the standard university contract prohibiting use of the source code in the classroom. Since that time, professors and students have largely had to be content with operating systems theory because no system that was small enough to be understandable yet large enough to be realistic has been available in source form.

To remedy this situation, several years ago I decided to write a new operating system from scratch that would be system-call compatible with UNIX but completely new inside. In addition to eliminating the licensing problems, this system would be written using modern software concepts such as structured programming, modularity, and file servers. UNIX itself was begun in the early 1970s when the main design issue was squeezing it onto a PDP-11, rather than making the code easy for others to read.

That work is now complete and has resulted in a system called MINIX (mini UNIX) because it leaves out some of the more esoteric system calls in an attempt to make the

system smaller and easier to understand. MINIX was originally written for the IBM PC, XT, and AT, but work is currently under way to port it to the 68000 and other computers. The system is written in C and some care has been taken in the design to make the port to small computers without memory management hardware as straightforward as possible. This point will be discussed in detail later in the paper.

To avoid confusion, it is worthwhile stating explicitly who MINIX is aimed at. There are two potential groups of users.

1. Professors, students, and others who are interesting in legally obtaining and studying the source code of a UNIX-like operating system.

2. People who would like to run a UNIX-like system (especially at home), but have not been able to afford it. Since MINIX does not require a hard disk, the set of potential users is much larger than for UNIX.

Thus MINIX does not really compete with UNIX. Rather, it fills a niche that is currently unoccupied.

For the first category (i.e., educational) users, several options have been provided. The system can be modified and maintained on an IBM PC with or without a hard disk, using itself, a version of UNIX, or even MS-DOS. It can also be cross compiled on a VAX or other time-shared computer running UNIX. Furthermore, the software distribution contains an interpreter for the IBM PC (including I/O) so that the resulting system can be run on a VAX or other computer, preferably a fast one, in case no real IBM PCs are available for students. The MINIX file system can also be modified and run on almost any computer, since it is structured as a free-standing file server. The file server can also be used in a network of diskless workstations.

For the second category (i.e., impoverished) users, several versions of the system have been configured. The normal ones run on 640K PCs with two floppy disks or 512K ATs with one floppy disk, but a special version has also been configured for 256K PCs with only one floppy disk. This version does not contain the C compiler, but is otherwise complete.

MINIX is system-call compatible with Version 7 UNIX for both practical and ideological reasons. On the practical side, I was unable to figure out how to make either 4.3 BSD or System V run on a 256K IBM PC with only 1 floppy disk. On the ideological front, many people (myself included) strongly believe that Version 7 was not only an improvement on all of its predecessors, but also on all of its successors, certainly in terms of simplicity, coherence and elegance. Users who prefer features to elegance should program in Ada† on a large IBM mainframe running MVS.

MINIX implements all the V7 system calls, except ACCT, LOCK, MPX, NICE, PHYS, PKON, PKOFF, PROFIL, and PTRACE. The other system calls are all implemented in full, and are exactly compatible with V7. In particular, FORK and EXEC are fully implemented, so MINIX can be configured as a normal multiprogramming system, with several background jobs running at the same time (memory permitting), and even multiple users.

The MINIX shell is compatible with the V7 (Bourne) shell, so to the user at the terminal, running MINIX looks and feels like running UNIX. Over 70 utility programs are part of the software distribution, including ar, basename, cat, cc, chmem, chmod, chown, cmp, comm, cp, date, dd, df, echo, grep, head, kill, ln, login, lpr, ls, make, mkdir, mkfs, mknod, mount, mv, od, passwd, pr, pwd, rev, rm, rmdir, roff, sh, size, sleep, sort, split, stty, su, sum, sync, tail, tar, tee, time, touch, tr, umount, uniq, update, and wc. A full-screen editor inspired by Emacs (think of it as nano-emacs), a full K&R compatible C compiler, and programs to read and write MS-DOS diskettes are also included. All of the sources of the operating system and these utilities, except the C compiler source (which is quite large and is available separately), are included in the software package.

In addition to the above utilities, over 100 library procedures, including stdio, are provided, again with the full source code.

To reiterate what was said above, all of this software is completely new. Not a single line of it is taken from, or even based on the AT&T code. I personally wrote from scratch the entire operating system and some of the utilities. This took about 3 years. My students and some other generous people wrote the rest. The C compiler is derived from the Amsterdam Compiler Kit (Tanenbaum et al., 1983), and was written at the Vrije Universiteit. It is a top-down, recursive descent compiler written in a compiler writing language called LLGEN and is not related to the AT&T portable C compiler, which is a bottom-up, LALR compiler written in YACC.

2. OVERVIEW OF THE MINIX SYSTEM ARCHITECTURE

UNIX is organized as a single executable program that is loaded into memory at system boot time and then run. MINIX is structured in a much more modular way, as a collection of processes that communicate with each other and with user processes by sending and receiving messages. There are separate processes for the memory manager, the file system, for each device driver, and for certain other system functions. This structure enforces a better interface between the pieces. The file system cannot, for example, accidentally change the memory manager’s tables because the file system and memory manager each have their own private address spaces.

These system processes are each full-fledged processes, with their own memory allocation, process table entry and state. They can be run, blocked, and send messages, just as the user processes. In fact, the memory manager and file system each run in user space as ordinary processes. The device drivers are all linked together with the kernel into the same binary program, but they communicate with each other and with the other processes by message passing.

When the system is compiled, four binary programs are independently created: the kernel (including the driver processes), the memory manager, the file system, and init (which reads /etc/hosts and forks off the login processes). In other words, compiling the system results in four distinct a.out files. When the system is booted, all four of these are read into memory from the boot diskette.

It is possible, and in fact, normal, to modify, recompile, and relink, say, the file system, without having to relink the other three pieces. This design provides a high degree of modularity by dividing the system up into independent pieces, each with a well-defined function and interface to the other pieces. The pieces communicate by sending and receiving messages.
The various processes are structured in four layers:

4. The user processes (top layer).
3. The server processes (memory manager and file system).
2. The device drivers, one process per device.
1. Process and message handling (bottom layer).

Let us now briefly summarize the function of each layer.

Layer 1 is concerned with doing process management including CPU scheduling and interprocess communication. When a process does a SEND or RECEIVE, it traps to the kernel, which then tries to execute the command. If the command cannot be executed (e.g., a process does a RECEIVE and there are no messages waiting for it), the caller is blocked until the command can be executed, at which time the process is reactivated. When an interrupt occurs, layer 1 converts it into a message to the appropriate device driver, which will normally be blocked waiting for it. The decision about which process to run when is also made in layer 1. A priority algorithm is used, giving device drivers higher priority over ordinary user processes, for example.

Layer 2 contains the device drivers, one process per major device. These processes are part of the kernel’s address space because they must run in kernel mode to access I/O device registers and execute I/O instructions. Although the IBM PC does not have user mode/kernel mode, most other machines do, so this decision has been made with an eye toward the future. To distinguish the processes within the kernel from those in user space, the kernel processes are called tasks.

Layer 3 contains only two processes, the memory manager and the file system. They are both structured as servers, with the user processes as clients. When a user process (i.e., a client) wants to execute a system call, it calls, for example, the library procedure read with the file descriptor, buffer, and count. The library procedure builds a message containing the system call number and the parameters and sends it to the file system. The client then blocks waiting for a reply. When the file system receives the message, it carries it out and sends back a reply containing the number of bytes read or the error code. The library procedure gets the reply and returns the result to the caller in the usual way. The user is completely unaware of what is going on here, making it easy to replace the local file system with a remote one.

Layer 4 contains the user programs. When the system comes up, init forks off login processes, which then wait for input. On a successful login, the shell is executed. Processes can fork, resulting in a tree of processes, with init at the root. When CTRL-D is typed to a shell, it exits, and init replaces the shell with another login process.

3. LAYER 1 - PROCESSES AND MESSAGES

The two basic concepts on which MINIX is built are processes and messages. A process is an independently schedulable entity with its own process table entry. A message is a structure containing the sender’s process number, a message type field, and a variable part (a union) containing the parameters or reply codes of the message. Message size is fixed, depending on how big the union happens to be on the machine in question. On the IBM PC it is 24 bytes.

Three kernel calls are provided:
- RECEIVE(source, &message)
- SEND(destination, &message)
- SENDREC(process, &message)

These are the only true system calls (i.e., traps to the kernel). RECEIVE announces the willingness of the caller to accept a message from a specified process, or ANY, if the RECEIVER will accept any message. (From here on, “process” also includes the tasks.) If no message is available, the receiving process is blocked. SEND attempts to transmit a message to the destination process. If the destination process is currently blocked trying to receive from the sender, the kernel copies the message from the sender’s buffer to the receiver’s buffer, and then marks them both as runnable. If the receiver is not waiting for a message from the sender, the sender is blocked.

The SENDREC primitive combines the functions of the other two. It sends a message to the indicated process, and then blocks until a reply has been received. The reply overwrites the original message. User processes use SENDREC to execute system calls by sending messages to the servers and then blocking until the reply arrives.

There are two ways to enter the kernel. One way is by the trap resulting from a process’ attempt to send or receive a message. The other way is by an interrupt. When an interrupt occurs, the registers and machine state of the currently running process are saved in its process table entry. Then a general interrupt handler is called with the interrupt number as parameter. This procedure builds a message of type INTERRUPT, copies it to the buffer of the waiting task, marks that task as runnable (unblocked), and then calls the scheduler to see who to run next.

The scheduler maintains three queues, corresponding to layers 2, 3, and 4, respectively. The driver queue has the highest priority, the server queue has middle priority, and the user queue has lowest priority. The scheduling algorithm is simple: find the highest priority queue that has at least one process on it, and run the first process on that queue. In this way, a clock interrupt will cause a process switch if the file system was running, but not if the disk driver was running. If the disk driver was running, the clock task will be put at the end of the highest priority queue, and run when its turn comes.

In addition to this rule, once every 100 msec, the clock task checks to see if the current process is a user process that has been running for at least 100 msec. If so, that user is removed from the front of the user queue and put on the back. In effect, compute bound user processes are run using a round robin scheduler. Once started, a user process runs until either it blocks trying to send or receive a message, or it has had 100 msec of CPU time. This algorithm is simple, fair, and easy to implement.

4. LAYER 2 - DEVICE DRIVERS

Like all versions of UNIX for the IBM PC, MINIX does not use the ROM BIOS for input or output because the BIOS does not support interrupts. Suppose a user forks off a compilation in the background and then calls the editor. If the editor tried to read from the terminal using the BIOS, the compilation (and any other background jobs such as printing) would be stopped dead in their tracks waiting for the next character to be typed. Such behavior may be acceptable in the MS-DOS world, but it certainly is not in the UNIX world. As a result, MINIX contains a complete set of drivers that duplicate the functions of the BIOS. Like the rest of MINIX, these drivers are written in C, not assembly language.

This design has important implications for running MINIX on PC clones. A clone
whose hardware is not compatible with the PC down to the chip level, but which tries to
hide the differences by making the BIOS calls functionally identical to IBM's will not run
an unmodified MINIX because MINIX does not use the BIOS.

Each device driver is a separate process in MINIX. At present, the drivers include the
clock driver, terminal driver, various disk drivers (e.g., RAM disk, floppy disk), and
printer driver. Each driver has a main loop consisting of three actions:

1. Wait for an incoming message.
2. Perform the request contained in the message.
3. Send a reply message.

Request messages have a standard format, containing the opcode (e.g., READ, WRITE, or
IOCTL), the minor device number, the position (e.g., disk block number), the buffer
address, the byte count, and the number of the process on whose behalf the work is being
done.

As an example of where device drivers fit in, consider what happens when a user
wants to read from a file. The user sends a message to the file system. If the file system
has the needed data in its buffer cache, they are copied back to the user. Otherwise, the
file system sends a message to the disk task requesting that the block be read into a buffer
within the file system's address space (in its cache). Users may not send messages to the
tasks directly. Only the servers may do this.

MINIX supports a RAM disk. In fact, the RAM disk is always used to hold the root
device. When the system is booted, after the operating system has been loaded, the user is
instructed to insert the root file system diskette. The file system then sees how big it is,
allocates the necessary memory, and copies the diskette to the RAM disk. Other file sys-
tems can then be mounted on the root device.

This organization puts important directories such as /bin and /tmp on the fastest dev-

cice, and also makes it easy to work with either floppy disks or hard disks or a mixture of
the two by mounting them on /usr or /user or elsewhere. In any event, the root device is
always in the same place.

In the standard distribution, the RAM disk is about 240K, most of which is full of
parts of the C compiler. In the 256K system, a much smaller RAM disk has to be used,
which explains why this version has no C compiler: there is no place to put it. (The /usr
diskette is completely full with the other utility programs and one of the design goals was to
make the system run on a 256K PC with 1 floppy disk.) Users with an unusual configura-
tion such as 256K and three hard disks are free to juggle things around as they see fit.

The terminal driver is compatible with the standard V7 terminal driver. It supports
cooked mode, raw mode, and cbreak mode. It also supports several escape sequences,
such as cursor positioning and reverse scrolling because the screen editor needs them.

The printer driver copies its input to the printer character for character without modifi-
cation. It does not even convert line feed to carriage return + line feed. This makes it
possible to send escape sequences to graphics printers without the driver messing things up.
MINIX does not spool output because floppy disk systems rarely have enough spare disk
space for the spooling directory. Instead one normally would print a file f by saying

lpr <f &
to do the printing in the background. The lpr program insert carriage returns, expands tabs, and so on, so it should only be used for straight ASCII files. On hard disk systems, a spooler would not be difficult to write.

5. LAYER 3 - SERVERS

Layer 3 contains two server processes: the memory manager and the file system. They are both structured in the same way as the device drivers, that is a main loop that accepts requests, performs them, and then replies. We will now look at each of these in turn.

The memory manager's job is to handle those system calls that affect memory allocation, as well as a few others. These include FORK, EXEC, WAIT, KILL, and BRK. The memory model used by MINIX is exceptionally simple in order to accommodate computers without any memory management hardware. When the shell forks off a process, a copy of the shell is made in memory. When the child does an EXEC, the new core image is placed in memory. Thereafter it is never moved. MINIX does not swap or page.

The amount of memory allocated to the process is determined by a field in the header of the executable file. A program, chmem, has been provided to manipulate this field. When a process is started, the text segment is set at the very bottom of the allocated memory area, followed by the data and bss. The stack starts at the top of the allocated memory and grows downward. The space between the bottom of the stack and the top of the data segment is available for both segments to grow into as needed. If the two segments meet, the process is killed.

In the past, before paging was invented, all memory allocation schemes worked like this. In the future, when even small microcomputers will use 32-bit CPUs and 1M x 1 bit memory chips, the minimum feasible memory will be 4 megabytes and this allocation scheme will probably become popular again due to its inherent simplicity. Thus the MINIX scheme can be regarded as either hopelessly outdated or amazingly futuristic, as you prefer.

The memory manager keeps track of memory using a list of holes. When new memory is needed, either for FORK or for EXEC, it searches the hole list and takes the first hole that is big enough (first fit). When a process terminates, if it is adjacent to a hole on either side, the process' memory and the hole are merged into a bigger hole.

The file system is really a remote file server that happens to be running on the user's machine. However it is straightforward to convert it into a true network file server. All that needs to be done is change the message interface and provide some way of authenticating requests. (In MINIX, the source field in the incoming message is trustworthy because it is filled in by the kernel.) When running remote, the MINIX file server maintains state information, like RFS and unlike NFS.

The MINIX file system is similar to that of V7 UNIX. The i-node is slightly different, containing only 9 disk addresses instead of 13, and only 1 time instead of 3. These changes reduce the i-node from 64 bytes to 32 bytes, to store more i-nodes per disk block and reduce the size of the in-core i-node table.

Free disk blocks and free inodes are kept track of using bit maps rather than free lists. The bit maps for the root device and all mounted file systems are kept in memory. When a file grows, the system makes a definite effort to allocate the new block as close as possible to the old ones, to minimize arm motion. Disk storage is not necessarily allocated one block at a time. A minor device can be configured to allocate 2, 4 (or more) contiguous blocks whenever a block is allocated. Although this wastes disk space, these multiblock zones improve disk performance by keeping file blocks close together. The standard
parameters for MINIX as distributed are 1K blocks and 1K zones (i.e., just 1 block per zone).

MINIX maintains a buffer cache of recently used blocks. A hashing algorithm is used
to look up blocks in the cache. When an i-node block, directory block, or other critical
block is modified, it is written back to disk immediately. Data blocks are only written back
at the next SYNC or when the buffer is needed for something else.

The MINIX directory system and format is identical to that of V7 UNIX. File names
are strings of up to 14 characters, and directories can be arbitrarily long.

6. LAYER 4 - USER PROCESSES

This layer contains init, the shell, the editor, the compiler, the utilities, and all the user
processes. These processes may only send messages to the memory manager and the file
system, and these servers only accept valid system call requests. Thus the user processes
do not perceive MINIX to be a general-purpose message passing system. However, remov-
ing the one line of code that checks if the message destination is valid would convert it into
a much more general system (but less UNIX-like).

7. DOCUMENTATION

For a system one of whose purposes is teaching about operating systems, ample docu-
mentation is essential. For this reason I have written an ample textbook (more than 700
pages) treating both the theory and the practice of operating system design (Tanenbaum,
1987). The table of contents is as follows:

CHAPTERS
1. Introduction
2. Processes
3. Input/Output
4. Memory Management
5. File Systems
6. Bibliography and Suggested Readings

APPENDICES
A. Introduction to C
B. Introduction to the IBM PC
C. MINIX Users Guide
D. MINIX Implementers Guide
E. MINIX Source Code Listing
F. MINIX Cross Reference Map

The heart of the book is chapters 2-5. Each chapter deals with the indicated topic in the
following way. First comes a thorough treatment of the relevant principles (thorough
enough to be usable as a university textbook on operating systems). Next comes a general
discussion of how the principles have been applied in MINIX. Finally there is a procedure
by procedure description of how the relevant part of MINIX works in detail. The source
code listing of appendix E contains line numbers, and these line numbers are used
throughout the book to pinpoint the code under discussion. The source code itself contains
more than 3000 comments, some more than a page long. Studying the principles and
seeing how they are applied in a real system gives the reader a better understanding of the subject than either the principles or the code alone would.

Appendices A and B are quickie introductions to C and the IBM PC for readers not familiar with these subjects. Appendix C tells how to boot MINIX, how to use it, and how to shut it down. It also contains all the manual pages for the utility programs. Most important of all, it gives the super-user password.

Appendix D is for people who wish to modify and recompile MINIX. It contains a wealth of nutsy-boltsy information about everything from how to use MS-DOS as a development system, to what to do when your newly made system refuses to boot.

Appendix E is a full listing of the operating system, all 260 pages of it. The utilities (mercifully) are not listed.

8. DISTRIBUTION OF THE SOFTWARE
The software distribution is being done by Prentice-Hall. Four packages are available. All four contain the full source code; they differ only in the configuration of the binary supplied. The four packages are:

- 640K IBM PC version
- 256K IBM PC (no C compiler)
- IBM PC-AT (512K minimum)
- Industry standard 9-track tape

The 640K version will also run on 512K systems, but it may be necessary to chmem parts of the C compiler to make it fit. The tape version is the only one containing the IBM PC simulator and other software needed for classroom use on a VAX or other time sharing machine. The software packages do not include the book.

If there is sufficient interest, a newsgroup net.minix will be set up. This channel can be used by people wishing to contribute new programs, point out and correct bugs, discuss the problems of porting MINIX to new systems, etc.

9. ACKNOWLEDGEMENTS
I would like to thank the following people for contributing utility programs and advice to the MINIX effort: Martin Atkins, Erik Baalbergen, Charles Forsyth, Richard Gregg, Michiel Huisjes, Patrick van Kleef, Adri Koppes, Paul Ogilvie, Paul Polderman, and Robert van Renesse. Without their help, the system would have been far less useful than it now is.
