NEW IN OLD
EVALUATION OF A MULTIDISCIPLINARY INTEGRATED CARE MODEL AND STUDIES IN RESIDENTIAL CARE HOMES

Marijke Boorsma-Meerman
The studies presented in this thesis were performed at the EMGO Institute of the VU University Medical Center, Amsterdam, The Netherlands. The EMGO Institute participates in the Netherlands school of Primary Care Research (CaRe), which was re-acknowledged in 2006 by the Royal Academy of Arts and Sciences (KNAW).

The initiative for this research project underlying this thesis was financially supported by the Netherlands organisation for health research and development (ZonMw).

CHAPTER 1
GENERAL INTRODUCTION

M. Boorsma-Meerman
The focus of this thesis is on the effects of introducing a multidisciplinary integrated care approach on quality of care and associated costs for residents in Dutch residential care homes and studies on incidences of mental dysfunctions. In this introduction we present the description of the problems faced in care for elderly people living in residential care homes. We describe the multidisciplinary integrated care approach introduced in this study and the relation of this approach to the Chronic Care Model. At last we present the studies on incidences of mental dysfunction for residents in Dutch residential care homes and nursing homes and list the main research questions addressed in this thesis.

The quality of care provided in residential care homes is under pressure worldwide. Facilities are frequently understaffed, and the complexity of care needed by residents increases while expertise of staff does not necessarily keep pace. Although most care organizations want to innovate and improve quality of care, many lack expertise or financial resources needed to do so. Family physicians are responsible for medical care in residential care homes in the Netherlands. However, they do not regard themselves as suited for systematic management of chronic diseases and disabilities associated with frail health. Family physicians routinely experience the tyranny of the urgent. Cooperation with other professionals in the field as Elderly Care physicians is scarce. Lack of attention for self management support for elderly people with multiple chronic diseases and their families and lack of optimal attention for their wishes results too often in unfavourable outcomes.

In the Netherlands, around 10% of all the elderly aged 75 and over live in 1131 residential care homes (115,000) or in 479 nursing homes (60,000). These homes were established to offer sheltered living for elderly people who are disabled but still relatively healthy. Because of the growing elderly population, the characteristics of elderly people living in residential care homes have become more comparable to those of people in nursing homes, who need complex care. Nowadays over 70% of the residents in residential care homes need professional care, such as assistance with activities of daily living, nursing care (e.g., medication, wound care) and housekeeping. They have multiple chronic diseases and associated disabilities. Staff in residential care homes mostly include nurse-assistants and even lower educated personnel and a house manager.
ABOUT COSTS

Chronic disablement associated with aging is the main cost driver for national health care costs. Care facilities for elderly make up about one fifth of the costs of the Dutch health care system and are the second largest cost category after hospital care. Within these costs residential care homes are the largest cost category and absorb about 40% of this budget. (45,46)

CONCERNS ABOUT QUALITY OF CARE

Already in 1995 the National Health Council stressed the importance of improving the quality of care for chronic patients by a shared disease management plan of involved health professionals with emphasis on clearly defined medical responsibilities, and development of shared management protocols. (40,43) In a report, published in 2003, on the state of health care by the Dutch Healthcare Inspectorate alarming conclusions were drawn after rigorous investigations on the state of Transmural Integrated Care in the Netherlands. (30) The report stated that patients with chronic disorders are at risk because of the lack of shared management by health professionals and health institutes, and unclear demarcation of medical responsibilities. This was recognised by the minister of Welfare, Health and Culture Affairs in his answer to the parliament. (52)

A MULTIDISCIPLINARY CARE APPROACH

In order to change the present situation a multidisciplinary integrated care approach is strongly recommended. (30,40,43,52) Beneficial effects of such approaches were reported among stroke patients and among type 2 diabetes patients. (15,35,40,52) However, no studies were performed yet to evaluate the effects of a multidisciplinary integrated care approach on quality of care and costs for residents in residential care homes in the Netherlands.

THE STUDIED INTERVENTION

In this study we investigated the effects of a multidisciplinary integrated care approach. The approach we applied in this study consists of several elements. First, structural and computerised multidimensional geriatric screening by trained staff. Second, patient tailored care plans made by staff together with residents, and/or relatives. Third, multidisciplinary meetings including nursing staff, family physicians, Elderly Care physicians, and psychologists. Fourth, the frailest residents with complex needs are offered a multidisciplinary consultation by an Elderly Care physician and psychologist.

RELATION TO THE CHRONIC CARE MODEL

The multidisciplinary integrated care approach presented in this study can be seen as a variation of the Chronic Care Model of Wagner and Bodenheimer. (6,54) Like the chronic care model it comprises the following key components: risk and care-need assessment of each resident; constructing a care plan together with the resident and/or the family; empowerment of the nurse-assistant and the resident and/or family by giving information and education; monitoring how the resident is doing over time by repeating the assessment at least every 6 months, and revising the care plan as needed. The Chronic Care Model is designed for primary care and deals with various care providers and health institutes. It is tailored on community dwelling chronically ill of all ages. Our approach is tailored on vulnerable elderly people living in residential care homes. The studied homes are under the umbrella of one single care organization. The residents are often hampered in self management by cognitive impairment. Therefore we wanted to empower the nurse-assistant in relation to monitoring and coordination of care. The individual interaction between the empowered nurse-assistant and informed resident and/or family in this setting can make the difference and may be the cue key for improved outcomes (figure 1)

ABOVE THE GERIATRIC ASSESSMENT INSTRUMENT

For the structural and computerised multidimensional geriatric screening our choice was for the Resident Assessment Instrument (RAI), because it was found to be the most tested, evaluated and validated tool that presently exists. (28,29) RAI was developed in 1990 on the request of the United States Congress after years of concerns about the quality of care in nursing homes. (10,13,17,25,36,39,53) Achterberg reported significant improvements in care history, care planning, and coordination of care after the implementation of the Resident Assessment Instrument. (1,2) Since the development of RAI and the mandatory implementation in nursing homes in the United States it found its way to some 50 countries in all inhabited continents. (www.interRAI.org) Recently, the Dutch Health Department supported the development of a web application of the Long-Term care Facility version of the Resident Assessment Instrument (inter RAI-LTCF). This instrument has two main, and interconnected, parts: The Minimum Data Set (MDS) and a set of Client Assessment Protocols (CAPs). The MDS is a form with 120 items about 13 domains of health, wellbeing, and functioning of the client. (Appendix 1) The interconnected CAPs identify problems in 18 areas that may need specific care planning. (Appendix 2) The identified problems guide the design of an individualised care plan with the intention to improve or maintain the patient’s functional health. The CAPs contain the state-of-the-art approach for the identified problem. In our study, we have applied this web application and showed that it has good applicability. The inter RAI-LTCF contains a number of validated scales: the Cognitive Performance Scale (CPS), the Activities of Daily Life Scale (ADL scale), the Depression Rating Scale (DRS), the Changes in Health End-stage disease and Symptoms and Signs Scale (CHESS), and the Revised Social Engagement Scale (RISE). (23,26,31,37,38) These scales present a direct overview of the health status of the client (Appendix 3) All the RAI versions come with a Manual (also digital) that provides extensive information, definitions, examples, and timeframes that help to complete reliable assessments. In addition, data from the web based inter RAI- LTCF is used to make a three monthly overview, for each facility that participates, of 32 risk adjusted indicators of quality of care. These indicators
are compared to a benchmark made out of all the residents of residential care homes in the Netherlands using the inter RAI LTCF (4:18-20;24-26;27,31;34;44;54). Management can use this overview to improve specific areas of care. For example, if the number of fall incidents is substantially higher compared to the average (benchmark), management can decide on measures to improve safety in a particular home. (Appendix 4)

Our hypothesis is that introduction of a multidisciplinary care approach has positive effects on quality of care and is cost effective. The main research questions for this study are:

1. Does the introduction of a multidisciplinary integrated care approach increase the quality of care for elderly people living in Dutch residential care homes?

The study related to this question is described in CHAPTER 3

2. Is the introduction of a multidisciplinary care approach cost effective?

The study related to this question is described in CHAPTER 5

3. What are the facilitating and impeding factors in the initial and maintenance phase of a geriatric assessment instrument as part of a multidisciplinary integrated care approach in Dutch residential care homes?

The study related to this question is described in CHAPTER 5

OTHER STUDIES PRESENTED IN THIS THESIS

Besides the main research questions also the incidences of mental dysfunctions like depression and delirium and their associated risk factors are studied in residents of Dutch nursing homes and residential care homes. (chapters 6,7 and 8) Mental dysfunction, such as depression or delirium play an important role in the vulnerability of elderly people, especially in long term care facilities like nursing homes and residential care homes. (14;16;32)

Both conditions are not easy to recognize and especially difficult in elderly people who are cognitively impaired. The available inter RAI-LTCF data in the VU database enabled us to study the incidence and associated risk factors of both mental conditions for a total of 3,672 residents of 6 nursing homes and 23 residential care home. This cohort provides a strong external validity as residents are not excluded systematically and data collection does not depend on informed consent but on routine daily care.

Our hypothesis is that the incidence of mental dysfunctions like depression and delirium is substantial and the associated risk factors will be different between the two settings. The main research questions for these studies are:

1. What is the incidence of depression in Dutch residents for nursing homes compared with the incidence for residents in Dutch residential care homes and what are the associated risk factors in both settings? The study related to this question is described in CHAPTER 6

2. Is there an under-diagnosing of depression in demented residents of Dutch residential care homes? The study related to this question is described in CHAPTER 7

3. What is the prevalence and incidence of delirium in the residents of Dutch residential care homes compared to the residents of Dutch nursing homes? What are the associated risk factors in both settings? The study related to this question is described in CHAPTER 8

ABSTRACT

BACKGROUND The objective of this article is to describe the design of a study to evaluate the clinical and economic effects of a multidisciplinary integrated care model on functional health, quality of care and quality of life of persons living in residential care homes.

METHODS This study concerns a cluster randomized controlled clinical trial among five intervention homes and five usual care homes in the North-West of the Netherlands with a total of over 500 residents. All persons who are not terminally ill, are able to be interviewed and sign informed consent are included. For cognitively impaired persons family proxies will be approached to provide outcome information. The Chronic care Model consists of several elements: (1) Trained staff carries out a multidimensional assessment of the patients functional health and care needs with the inter RAI Long Term Care Facilities instrument (LTCF). Computerization of the inter RAI-LTCF produces immediate identification of problem areas and thereby guides individualized care planning. (2) The assessment outcomes are discussed in a multidisciplinary meeting with the nurse-assistant, primary care physician, elderly care physician and Psychotherapist and if necessary other members of the care team. The multidisciplinary meeting presents individualized care plans to manage or treat modifiable disabilities and risk factors. (3) Consultation by an nursing home physician and psychotherapist is offered to the frailest residents at risk for nursing home admission (according to the inter RAI-LTCF). Outcome measures are Quality of Care indicators (LTCF based), Quality Adjusted Life Years (Euroqol), Functional health (SF12, COOP-WONCA), Disability (GARS), Patients care satisfaction (QUOTE), hospital and nursing home days and mortality, health care utilization and costs.

DISCUSSION This design is unique because no earlier studies were performed to evaluate the effects and costs of this multidisciplinary integrated care Model for disabled persons in residential care homes on functional health and quality of care.

Trail registration number: ISRCTN11076857
BACKGROUND

Publishing the design of a study and the results of the pilot is seen as useful by various publishers. There are several reasons mentioned in earlier publications, such as: the possibility to compare the originally intended and hypothesized objectives and the final outcomes. Some authors mention that publishing the design and pilot results of a study prevents not publishing the adverse or negative outcomes. (1,2) A positive effect of publishing a design article is prevention of bias (1) and publishing the pilot results provides a better insight in the choices for particular instruments and interventions. (1)

CARE NEEDS OF ELDERLY IN RESIDENTIAL CARE HOMES Persons in the residential care homes suffer greatly from (multiple) chronic diseases and associated disablement. (3) Over the last decades, Dutch residents of residential care homes have become older and more disabled and show more and more resemblance with nursing home patients. (4,5) Primary care physicians are responsible for the medical treatment of persons living in residential care homes. However, primary care physicians are often unable to handle the complex medical problems. (6,7) Many health problems go unnoticed by the primary care physicians. (8) Primary care physicians do not regard themselves to be suited for systematic management and long-term monitoring for chronic diseases and disabilities associated with frail health. (9)

A MULTIDISCIPLINARY INTEGRATED CARE APPROACH The Chronic care Model is based on 3 elements: coordination of care, guiding of the care process and empowerment of the patient. (10) This model is strongly recommended to improve the health and quality of life of the chronically ill. (11,12,13) Beneficial effects of chronic care were reported among stroke patients and among diabetes mellitus type 2 patients. (14,15,16) However no studies were performed yet to evaluate the effects on functional health, quality of care and the cost-effectiveness of chronic care for disabled persons in residential care homes. We use the concept of chronic care but not focused on the diseases level but on the disabilities and handicaps they cause and call it a multidisciplinary integrated care approach. Already in 1995 the National health Council of the Netherlands stressed the importance of improving the quality of care for chronic patients by a shared chronic care of the health professionals involved, with clearly defined medical responsibilities, and the development of shared management protocols. (17)

CHRONIC DISORDERS AND DUTCH RESIDENTIAL CARE HOMES In our aging population the number of persons with a chronic disease is expected to increase from 1994-2015 with 25-60%. (18) In the Netherlands there are about 110.000 residents in residential care homes (4). Professional care is needed for 71% of the residents such as assistance with activities of daily living or mobility, nursing care (medication, wound care etc) and domestic help. Twelve percent of persons of 75 years and older live in a home for the elderly and 4% in a nursing home. (19) The quality of care in these homes is frequently discussed in national and international newspapers. The care organizations responsible for the quality of care given in residential care homes often do not have the tools to measure and improve quality of care. Scientific studies of quality of care for the elderly are rare.

COSTS Aging is costly for health care systems. About one third of the health care expenditures in industrialized countries involves persons of 70 years and older. Elderly are massive consumers of medication and occupy most of hospital beds. (3) Studies of comparable interventions and associated costs in residential care homes are absent. Nevertheless, we reanalyzed two meta-analyses of Stuck 2002 and Elkan 2000 on preventive effects of home visits to community dwelling elderly and selected only studies that focused on frail elderly 12 of 27 trials. (20,21) Six of these studies that reported on costs, found that preventive visits or outreaching geriatric management reduced care costs. (22) Objectives for this article were to describe the design of an evaluation study on the clinical and economical effects of a new chronic care model for residents in residential care homes.

METHODS

DESIGN A cluster randomized controlled clinical trial is carried out among five intervention homes and five usual care residential care homes in the north-west of the Netherlands that comprise over five hundred residents. There is a follow up of six months (Figure 1). The ethical committee of the VU medical center approved the study.

Figure 1: Flow chart of the design
The randomization is carried out on home matched by percentage of psycho geriatric (i.e. cognitive impaired) residents. The care services and type of disability in homes with a high percentage of psycho geriatric patients are likely to differ depending on how many residents need psycho geriatric care. So, the homes were first ranked on percentage of psycho geriatric patients. The two homes with the highest percentage of psycho geriatric patients were than matched, and so on. Next, we checked the risk of imbalance in numbers following Pocock’s recommendations. If the difference in number of intervention and control residents would be >15% (75 or more) the randomization should be repeated until the imbalance was 15% or less. Homes were all ordered on the percentage psycho-geriatric patients and numbered from rank one to rank 10. In this way matched homes are ranked after each other, one having an even and the other an uneven number. Randomization was carried out using Pocock’s first column in his random numbers table. If the table’s first number is even, the even number of first matched home is assigned the intervention. If the next table number is uneven, the uneven number of the next matched couple is assigned the intervention. And so on until all matched couples are assigned.

Eligibility of Residents
All residents were eligible except the terminally ill. Terminally ill is defined as death expected within six months. A family proxy of cognitive impaired persons was approached to provide outcome information.

Procedure
All residents from the usual care homes as well as from the intervention homes receive an invitation letter and an informed consent form two weeks before the start of the study. If the resident is not able to understand the information and/or to sign the informed consent papers a close family member will be invited to participate and provide proxy information on the outcomes. All eligible persons who sign an informed consent are going to be visited by an interviewer of the VU medical centre for an interview on their health and resource use. Table 1 provides an over-view of the measurements.

The Chronic care Model is based on 3 elements: coordination of care, guiding of the care process and empowerment of the patient. (10) A limitation of chronic care for patients with multi-morbidity is the single-disease oriented perspective. Therefore in this project among elderly with mostly multiple morbidity, we choose an expanded multidimensional or bio psychosocial perspective which corresponds to the International Classification of Functioning, Disability and Health. (24) For our target population we defined chronic care as improving or maintaining the functional health status by providing continuity of care, being patient oriented, generating multidimensional health data on residents, executed by appropriately trained professionals who design a shared chronic care plan and is ICT supported. In the intervention homes we will make multidisciplinary integrated care operational in the process of care in three sequential steps: Firstly a three-monthly in-home systematic and computerized multidimensional assessment of all residents by staff (nurse) who systematically identifies the functional health status and care needs. For this purpose, the inter RAI-LTCF instrument will be used. (25) The Resident Assessment Instrument (RAI) was originally designed as a minimum data set to assess the health needs of nursing home residents. For the residential care homes we use the inter RAI-LTCF (Long Term Care Facility) version. The inter RAI LTCF provides a comprehensive overview of the person’s physical, psychological, behavioral and social status. Moreover it indicates a global level of care need which distinguishes persons who do not need care, from those who need personal care, home care, extramural home care or nursing home care. The web based inter RAI-LTCF produces an easy and direct overview of problems in 18 areas that may need specific care planning. The identified problem areas guide the design of an optimal individualized care plan. In a multidisciplinary team, all disciplines involved in care for the resident, will participate in regular meetings in order to evaluate the inter RAI LTCF findings and design and monitor the (tailor made) care-plan. The care plan aims to improve or maintain the functional health status and is focused at modifiable risk factors of the resident (Table 2). Secondly, the assessment outcomes are discussed in a multidisciplinary meeting (MM) in the homes with the primary care physician, nursing home physician, nurse, Psychotherapist and other involved disciplines. In the MM an individualized care plan is made to treat modifiable disabilities and identify and eliminate (when possible) risk factors. Thirdly, a multidisciplinary consultation is offered to the frailest residents with complex health care problems. They are identified by the level of expected resource utilization. (26) In addition, the computerized inter RAI LTCF also provides process-supporting information technology as well as indicators about the functioning and implementation of the care plans.

OUTCOMES AND MEASUREMENTS (TABLE 1)

Primary outcomes
1. Quality of care as measured with the risk adjusted criteria (27),
2. Quality Adjusted Life Years using health utilities is measured with the Euroqol (28,29),
3. Functional health is measured by COOP-WONCA charts (30,31) (Nelson 1983, Van Weel 1995) and Short Form 12 item version. (32)

Secondary outcomes
4. Care satisfaction of residents is measured by the brief QUOTE, which wording was slightly adapted to fit the institutional setting (33).
5. ADL and IADL disability is measured by GARS (34).
6. (Days until) placement in a nursing home is surveyed and crosschecked at institutes.
7. (Acute) hospitalization is surveyed and cross-checked at the local hospital which covers 95% of all admissions in the region.
8. (Days until) mortality is checked in the administration of the homes.

Economic outcomes
9. Health care utilization data are collected by patient or proxy interview at baseline and patient records over 6 months.
SAMPLE SIZE CALCULATION are based on the expected effects of the intervention on the main outcome measures concerning quality of care and functional health. In the following sample size calculations we used an alpha of 0.05, power of 80% and inflation of 10% because of anticipated intra-cluster correlation in the residential care homes. Regarding health related quality of life, Cohen’s D effect size ranged from 0.5 to 3.8 in our meta-analysis. (22) To detect a fair benefit, i.e. effect size = 0.5, a minimum of 64 persons is needed in each group (35). For functional health and disability we anticipate on a comparable effect-size and consequently identical sample size. Furthermore if we assume a dropout rate of 15% during the 6 months follow-up we need to include at least 100/85 x 64 x 110% = 82 persons in each group.

DATA ANALYSIS Effect analyses will be performed both on ‘intention to treat’ and per protocol principles. Differences between intervention and usual care patients at 6 months on the outcome measures (risk adjusted inter RAI LTCF based Quality indicators, Euro QoL, functional health and disability) will be compared between the intervention and control group by both univariate and multivariate techniques. We will use the multivariate technique to adjust for possible differences in baseline scores and background variables between the intervention and control groups. Dropout and loss to follow up will be described. Potential effect-modification will be explored. Especially, possible differential effects of multidisciplinary integrated care will be explored across residents with complex and simple health problems.

PROCESS EVALUATION The process evaluation involves assessing the extent to which the intervention program is performed according to protocols, the nature of the recommendations made to the participants of the multidisciplinary meeting, compliance with these recommendations, physicians and therapists judgments about the intervention program and recommendations. Data on these topics are collected using structured registration forms during the intervention. Finally, semi-structured interviews will be held with the participating nurses, primary care physicians, and elderly care physicians at the end of the intervention period in order to record their experiences and opinions on the new multidisciplinary integrated care approach.

ECONOMIC EVALUATION Cost data are collected by resident interview at base line, and at 6 months from a societal perspective and supplemented with resource use as registered within the home for the elderly. In case residents are cognitively impaired or not able anymore to be interviewed, proxies will be sought, preferably close family members. Only direct healthcare costs will be considered, because all patients have retired. Included cost categories are costs of consultations with the general practitioner, the nursing home physician. The randomization on level of the residential care homes may be a weak point of the design as specific cultural habits of the homes will not be equally distributed over the two groups. On the other hand, randomization of homes will prevent contamination of the intervention to usual care homes. The implementation of inter RAI LTCF demands a great effort on the part of the organization and outcomes are dependent on good use of the instrument.

DISCUSSION

In this paper we described the design of a randomized cost-effective trial of the effect of a multidisciplinary integrated care approach on residents of residential care homes. This study holds several unique elements. The intervention concerns continuity of care and identification of care needs of the residents. The use of inter RAI LTCF enables nurses to accurately diagnose the problems addressed within the complex clinical status of a frail elderly person. As a consequence, primary care physicians will be better informed about the health problems of their patients. This may enable effective chronic care. Finally, to persons with complex problems a multidisciplinary consultation is offered by an elderly care physician. The randomization on level of the residential care homes may be a weak point of the design as specific cultural habits of the homes will not be equally distributed over the two groups. On the other hand, randomization of homes will prevent contamination of the intervention to usual care homes. The implementation of inter RAI LTCF demands a great effort on the part of the organization and outcomes are dependent on good use of the instrument.

Sophisticated approaches are needed to improve the quality of care for elderly in residential care homes. We determined the effects of multidisciplinary integrated care on quality of care and quality of life for elderly people in residential care homes.

**METHODS** We performed a cluster randomised controlled trial involving 10 residential care homes in the Netherlands that included 340 participating residents with physical or cognitive disabilities. Five of the residential care homes applied multidisciplinary integrated care, and five provided usual care. The intervention, inspired by the disease management model and consisted of: a geriatric assessment of functional health every three months. The assessment included use of the Long-Term Care Facility version of the Resident Assessment Instrument by trained nurse-assistants to guide the design of an individualized care plan; discussion of outcomes and care priorities with the family physician, the resident and his or her family and monthly multidisciplinary meetings with the nurse-assistant, family physician, psychologist and elderly care physician to discuss residents with complex needs.

**RESULTS** Compared with the homes that provided usual care, the intervention homes had a significantly favourable sum score of the 32 quality of care indicators (mean difference -6.7, p = 0.009; a medium effect size of 0.72). They had significantly favourable scores for 11 of the 32 indicators of good care in the areas of communication, delirium, behaviour, continence, pain and use of antipsychotic agents.

**INTERPRETATION** Multidisciplinary integrated care resulted in improved quality of care for elderly people in residential care homes compared with usual care.

**TRIAL REGISTRATION:** ISRCTN11076857

INTRODUCTION

Quality of care provided in residential care homes is under pressure worldwide. Facilities are frequently understaffed, and the complexity of care needed by residents increases while expertise of staff does not necessarily keep pace. Although most care organizations want to innovate and improve quality of care, many lack the expertise or financial resources to do so. Family physicians are responsible for medical care in residential care homes in the Netherlands. However they do not regard themselves as suited for systematic management of chronic diseases and disabilities associated with frail health. About 10% of elderly people aged 75 or older in the Netherlands live in residential care homes. These homes were established to offer sheltered living for elderly people who are disabled but still relatively healthy. Because of the growing elderly population the characteristics of elderly people living in residential care homes have become more comparable to those of people in nursing homes, who need complex care. Residential care homes in the Netherlands are comparable to residential care facilities in Canada, are publically funded and are subject to governmental inspection and approval. Over 70% of the residents need professional care such as assistance with daily living, nursing care (e.g., medication, wound care) and housekeeping. They have multiple chronic diseases and associated disabilities. Effective interventions for chronic illnesses generally rely on a multidisciplinary team approach. The elements of this approach include structured geriatric assessment, protocol-based regulation of medication, support for self-reliance and intensive follow-up. The closely related Disease management model comprises coordination of care, steering of the care process and patient empowerment. This model is strongly recommended by Bodenheimer and colleagues to improve the health and quality of life of chronically ill patients. However, no studies have as yet been undertaken to evaluate the effects of disease management on functional health and quality of care for elderly people in residential care homes, who have physical and cognitive disabilities. We developed an approach to multidisciplinary integrated care inspired by the disease management model. The objective of this study was to determine the effects of Multidisciplinary Integrated Care on quality of care and quality of life for elderly people.

METHODS

The study was approved by the ethics committee of the VU University Medical Center in Amsterdam the Netherlands. All participating residents or their proxies provided written informed consent. Figure 1 shows the flow of participants through the study.

Figure 1: Flow of completed interviews of participants through the trial.
STUDY DESIGN AND PARTICIPANTS

After a pilot study in one residential care home, a cluster randomised controlled clinical trial was set up in 10 residential care homes belonging to the umbrella care organization Omring, a large home care and long term care provider in the Netherlands. The pilot home was excluded from the trial. Randomization was carried out at facility level; five homes were assigned to the intervention group and the other five to the usual care group. A total of 462 of the 10 homes were recruited from December 2006 until December 2007. The average number of residents in each home was 46 and staff included nurse-assistants and a house manager. All residents were listed in primary care practice, whose physician was responsible for their medical care. Residents who were terminally ill (as determined by staff or family physician) were excluded from the study. Participating residents in each home were visited by trained blinded interviewers at baseline and at six months. If the resident was unable to understand the questions a close family member was identified by staff and asked to act as proxy. The interview consisted of a computerized assessment of functional health, Activities of Daily Living, depression, cognition, satisfaction with care and use of medications. Proxies completed the interview except for the cognitive assessment which was replaced by a short form of the Informant Questionnaire on Cognitive Decline in the Elderly. The duration of the trial was relatively short because of a high risk for drop out owing to the extreme vulnerability of residents and because the umbrella care organisation intended to implement the care model in the control homes as well. A detailed description of the design was reported earlier.(14)

RANDOMIZATION Randomization was carried out on homes after matching for percentage of cognitively impaired residents, based on the assumption that a high percentage of such residents would affect care-related needs and services. In the matching procedure, the two homes with the highest percentage of cognitively impaired residents were matched, and so on. Randomization was carried out using the first column from Pocock’s random numbers table. (15)

INTERVENTION By adapting the principles of disease management we introduced the concept of multidisciplinary integrated care. This concept focused on identification and monitoring of the functional disabilities caused by chronic diseases. Its three basic elements correspond to those of the disease management model: monitoring of disabilities, coordination of care, and empowerment.(6) The third element is normally applied to patients only. However we wanted to empower nurse-assistants in relation to monitoring and coordination of care, given that they provided all basic nursing care. The model of multidisciplinary integrated care used in our study comprised five elements.

First, a geriatric multidimensional assessment of all residents was conducted every three months. The web based Long Term Care Facility version 9.0 of the Resident Assessment Instrument was used for this purpose.(16) The identified problem areas guide the design of individualised care plans that intend to improve or maintain functional health status (see appendix 1). Second the care plan was discussed with the resident, the resident’s family, and the family physician, and adapted to personal wishes. Third, residents with complex care needs were scheduled at least twice a year for a multidisciplinary meeting. Fourth, consultation by elderly care physician or psychologist was optional for the frailst residents with complex health care problems. Fifth, data from the web based Resident Assessment Instrument was used to provide an overview every three-month of 32 risk-adjusted quality-of-care indicators. These indicators were compared with benchmark values derived from data on all residents of residential care homes in the Netherlands obtained using this instrument.(17,18) Further details of the model of multidisciplinary integrated care are found in Appendix 1.

USUAL CARE For homes assigned to usual care the family physician was responsible for medical care and offered it on request. There was neither coordination nor structural planning of care. Multidisciplinary meetings were mostly not attended by the family physicians.

OUTCOME MEASURES

For the purpose of the evaluation, experienced, specially trained, blinded and supervised interviewers independently assessed the residents at baseline and six month later. The interviewers’ assessments were supplemented by systematic observations of staff and extraction of data from residents’ medical records (e.g. actual medication regimen).

PRIMARY OUTCOME MEASURES The first primary outcome was the sum score of the 32 risk-adjusted quality of care indicators, which were developed by Morris and showed good validity and reliability.(20) Appendix 5 shows the definitions of the quality-of-care indicators including their numerator and denominators. The quality-of-care indicators were originally based on observations recorded in the Long Term Care Facility assessment form. We incorporated the itemised observations needed to calculate these indicators in the assessments performed by our independently trained interviewers. Inter-rater reliability of the quality-of-care indicators between interviewers and nurse-assistants in the intervention homes was satisfactory (mean intra-cluster correlation single measure = 0.74). The sum score of the quality-of-care indicators was determined by he number of indicators per resident divided by the number of indicators applied to a resident. Indicators were calculated using mixed linear hierarchical models. Four of the 32 quality-of-care indicators (behaviour problem, bladder or bowel incontinence, pressure ulcer and use of antipsychotics) applied both to the group of residents as a whole and to high- and low- risk groups. We therefore calculated two sum scores, one for all 32 indicators and one for the 24 whole-group indicators after exclusion of the 8 that were broken down to apply to high- and low-risk groups. Of these 24 whole group indicators, on average 21 (standard deviation(SD) 6.6) applied to the residents. Of all 32 indicators, on average 22 (SD 6.1) applied to the residents. The relatively lower number of applicable indicators among all 32 indicators is due to the inclusion of the breakdown indicators which applied to a maximum of 50% of the residents. The Cronbach’s α of the sum score of the 24 whole-group indicators was 0.62. The lower the sum score the higher the quality of care. For the second primary outcome related quality of life was measured using short-form12 item version of the Rand Health Insurance Study questionnaire. Its properties were satisfactory when used by proxies which were important in our study because of the percentage of cognitively impaired residents (58.2%). (6) We also calculated the number of quality-adjusted-life-Years using the algorithm of Hatoum and colleagues. (19,20)

SECONDARY OUTCOME MEASURES The secondary outcome measures comprised 32 individual risk-adjusted quality-of-care indicators (described in appendix 4); activities of daily living as measured by the Groningen Activity Restriction Scale designed for elderly people (Appendix 4), quality of care from the perspective of the Elderly in activities of daily living as measured by the Groningen Activity Restriction Scale designed for elderly (22), hospital admissions and mortality as recorded by the interviewers or staff and cross-checked by the administration of the municipality.
PROCESS OUTCOMES Process outcomes comprised the percentage of residents with completed assessments; the number of multidisciplinary meetings held based on minutes of the meetings; the numbers of agreed on medical, nursing and social actions based on content analysis of care-plans; and opinions of participating professionals regarding the intervention protocol as obtained by interviews with staff and family physicians.

STATISTICAL ANALYSES

SAMPLE- SIZE CALCULATIONS Sample- size calculations were based on the expected effects of the intervention on quality of care and functional health using an alpha level of 0.05, a power of 80%, a drop out rate of 15% and an anticipated intra-cluster correlation of 0.05, based on Adams and colleagues, across the residential care homes.(24) To detect a fair benefit, (i.e. Cohen’s d effect size = 0.5), we estimated that the sample should include at least 82 residents in each of the two study groups.(25)

EFFECT ANALYSES Effect analyses were performed according to both intention-to-treat and per protocol principles. We accepted that the protocol was adhered to when the first two (obligatory) steps of the intervention were performed. We compared differences in the outcome measures over six months between the intervention and control group using multivariable techniques. We applied mixed models for the continuous outcomes using an unstructured covariance matrix for the longitudinal data. For the dichotomous outcomes we applied generalized estimating equations using a logit link and an exchangeable working correlation. In all effect analyses we adjusted for baseline imbalance (e.g., by age, sex, cognitive impairment, depression, disability, and interview by proxy). The analyses were done with multilevel specification if these variables showed significantly higher log-likelihood estimates. Because of our cluster randomised design (with randomization at the facility level), results of multilevel and “simple” analyses were compared for all outcomes. If higher-order clustering effects were present outcomes of the multilevel analyses were presented; if clustering was negligible, results of “simple” analyses were presented. The intraclass coefficient across homes was estimated by exchangeable working correlation for all individual (dichotomous) quality-of-care indicators. In all outcomes with pre-post measurements, the effect of interest was the group x time (pre-post) interaction effect. A p-value of 0.05 or less was considered to be significant.

PROCESS ANALYSES We evaluated the extent to which the intervention program was performed according to protocol, the nature of the recommendations of the multidisciplinary meeting, and the judgments of family physicians and staff about the intervention programmed.

RESULTS

SAMPLE AND FACILITY CHARACTERISTICS Baseline characteristics of the residents and facilities are described in Table 1. There was a small imbalance between the intervention group and the usual care group in the numbers of residents with cognitive impairment and in the numbers with clinical depression. The trial ended up unbalanced because one control home did not accept any new entries as result of an upcoming move to another location and because a second control home was in the middle of moving to a new building and could therefore recruit few residents for the study. Analyses without these homes did not change the results.

Note COPD = chronic obstructive pulmonary disease, IQR = interquartile range, SD = standard deviation. *Score of < 5 on the Memory Impairment Screen, or ≥ 3.6 on the short form of the Informant Questionnaire on Cognitive Deterioration. †Diagnosed by family physician or specialist.
PRIMARY OUTCOMES: Compared with residential care homes that provided usual care, the intervention homes had a significantly lower sum score of the 32 risk-adjusted quality-of-care indicators (mean difference -6.7; 95% confidence interval (CI) -8.69 to -4.71, \( p = 0.009 \); Cohen d effect size 0.72) (Table 2). Self reported quality of life did not differ between residents of control and intervention homes (Table 3).

SECONDARY OUTCOMES: The intervention homes had lower scores than the control homes for 30 of the 32 risk-adjusted indicators of quality of care; the scores for 11 of these 30 indicators had decreased significantly (Table 2). In the intention-to-treat analyses no differences in disability or quality of care as seen through residents’ eyes were found between the two groups of homes (Table 3). In the per-protocol analysis, residents in the intervention homes tended to be more positive about the quality of care over time than residents in the usual care homes (difference 1.8; \( p = 0.072 \)). The per-protocol analyses contrast, only 25% of the multidisciplinary meetings in the control homes were visited in 90% of the multidisciplinary meetings and the elderly care physician at 75%. By residents included in the study were discussed (Table 4). The family physician was present in the intervention homes during the study period, and the outcomes of assessment of 93 residents in the intervention homes. This proportion was less than we had aimed for and no differences in disability or quality of care as seen through residents’ eyes were found between the two groups of homes (Table 3).

PROCESS OF CARE: The first step of the protocol, assessment with the Long Term Care Facility version of the Resident Assessment Instrument, was completed for 55.2% of the residents in the intervention homes. This proportion was less than we had aimed for and was partly a result of implementation delay. Forty multidisciplinary meetings were held in the intervention homes during the study period, and the outcomes of assessment of 93 residents included in the study were discussed (Table 4). The family physician was present in 90% of the multidisciplinary meetings and the elderly care physician at 75%. By contrast, only 25% of the multidisciplinary meetings in the control homes were visited by the family physician. The number of recommended actions per resident was 3.67 in the intervention home meetings and 2.26 in the control home meetings. The expertise of staff was felt by 52.9% of staff and 54.5% of the family physicians to have increased after the intervention home meetings and 2.26 in the control home meetings. The expertise of the multidisciplinary meetings in the control homes was visited by the family physician. The number of recommended actions per resident was 3.67 in the intervention home meetings and 2.26 in the control home meetings. The expertise of staff was felt by 52.9% of staff and 54.5% of the family physicians to have increased after the intervention home meetings and 2.26 in the control home meetings. The expertise of staff was felt by 52.9% of staff and 54.5% of the family physicians to have increased after the intervention home meetings and 2.26 in the control home meetings.

ANCILLARY ANALYSES: We did not find effect-modification of the outcomes by age, sex or baseline disability.
Compared with usual care, our model of multidisciplinary integrated care resulted in substantially higher quality of care for elderly people in the involved residential care homes. Functional ability, hospital admission and health-related quality of life remained comparable between the two groups. According to the per-protocol analyses mortality was lower in the intervention homes and residents in the intervention homes were more positive about their quality of care. Owing to the short intervention period (six months), the full protocol was applied to less than half of the residents in the intervention homes. The training and empowerment of nurse-assistants, which was completed for all intervention homes, together with monitoring using the geriatric assessment instrument were likely to be the most important ingredients for improvement of the quality of care.

Earlier studies have reflected elements of our intervention. For example positive health effects on residents have been reported as a result of interdisciplinary geriatric primary care in American facilities.(26) Integrated and home-based geriatric care management was reported to improve quality of care and reduce use of acute care services in a high-risk group of low income elderly people living at home.(27) Use of the Home Care version of the Resident Assessment Instrument in primary care health centers in Hong Kong resulted in improvement in two of 13 functional outcomes.(28) Modest positive effects on well-being and on deterioration of functional skills were found in a multidisciplinary program in vulnerable older people living at home.(29,30)

INTERPRETATION Compared with usual care, our model of multidisciplinary integrated care resulted in substantially higher quality of care for elderly people in the involved residential care homes. Functional ability, hospital admission and health-related quality of life remained comparable between the two groups. According to the per-protocol analyses mortality was lower in the intervention homes and residents in the intervention homes were more positive about their quality of care. Owing to the short intervention period (six months), the full protocol was applied to less than half of the residents in the intervention homes. The training and empowerment of nurse-assistants, which was completed for all intervention homes, together with monitoring using the geriatric assessment instrument were likely to be the most important ingredients for improvement of the quality of care. Earlier studies have reflected elements of our intervention. For example positive health effects on residents have been reported as a result of interdisciplinary geriatric primary care in American facilities.(26) Integrated and home-based geriatric care management was reported to improve quality of care and reduce use of acute care services in a high-risk group of low income elderly people living at home.(27) Use of the Home Care version of the Resident Assessment Instrument in primary care health centers in Hong Kong resulted in improvement in two of 13 functional outcomes.(28) Modest positive effects on well-being and on deterioration of functional skills were found in a multidisciplinary program in vulnerable older people living at home.(29,30)

LIMITATIONS Our study was limited by the fact that our population was frail and comprised a high percentage of cognitively impaired residents. As a result a portion of the data was collected from interviews with proxies. The judgments of proxies may have differed from the residents’ judgments. Therefore, we adjusted for proxy interview and cognitive status in our analyses. The cluster randomization produced an imbalance between the intervention and control homes in the number of participating residents and in some of the functional characteristics of the residents at baseline. Although we adjusted for the
imbalance in functional characteristics, imbalance in the number of participating residents may have led to underpowered results. Variation across the intervention homes in the application of the complete protocol (3%-66%) was another limitation. This variation can be explained by financial and administrative issues during the study period. The financial obligations for residential care homes resulting from a new national funding system for residential care of elderly people caused uncertainty about job continuation, high turnover of managers, and new priorities of the homes in our study. Despite this limitation the improvement in quality of care at the homes in our study was substantial.

CONCLUSION

Our model of multidisciplinary integrated care resulted in improved quality of care for elderly people in residential care homes compared with usual care. The results of this study are applicable to elderly people in such settings as residential care homes and nursing homes and even elderly people living in the community. In primary care settings, it may be beneficial to have a model to monitor elderly people and those with chronic diseases, to prevent functional decline and admission to hospital for acute care. It is also important to have an instrument that not only delivers output on the patient level but also on the management level, to facilitate monitoring of quality of care by managers in a sector of health care that under enormous societal pressure to improve its performance.

ABSTRACT

OBJECTIVES The objective of this study was to evaluate the cost-effectiveness of a Multidisciplinary Integrated Care approach compared to usual care in Dutch residential homes.

METHODS The economic evaluation was conducted from a societal perspective alongside a 6 month, clustered, randomized controlled trial involving 10 Dutch residential care homes. Outcome measures included a quality of care weighted sum score, functional health (COOP WONCA) and Quality Adjusted Life-Years (QALY). Missing cost and effect data were imputed using multiple imputation. Bootstrapping was used to analyze differences in costs and cost-effectiveness.

RESULTS The sum score on risk indicators of quality of care, in the multidisciplinary integrated care group, was significantly lower than in usual care, indicating higher quality of care. The other primary outcomes showed no significant differences between the two groups. The costs of providing multidisciplinary integrated care were approximately €225 per patient. Total costs were €2,061 in the multidisciplinary integrated care group and €1,656 for the usual care group (mean difference €405, 95% -13 ; 826). However the difference between the two groups was not statistically significant. The probability that the multidisciplinary integrated care approach was cost-effective in comparison with usual care was 0.95 or more for ceiling ratios larger than at most €129 regarding patient related quality of care. Cost-effectiveness planes showed that the multidisciplinary integrated care approach did no show cost-effectiveness in comparison to usual care for the other outcomes.

INTERPRETATION Clinical effect differences between the groups were small but quality of care was significantly improved in the multidisciplinary integrated care group. Short term costs for multidisciplinary integrated care were not significantly higher. Future studies should focus on longer term economic and clinical effects.
INTRODUCTION

In nearly every country around the world, the proportion of people aged over 60 years is growing faster than any other age group. (1) Long-term care costs are largely affected by this increase because long-term care expenses tend to increase markedly with old age. (2) As the aging population intensifies its demand and uptake of healthcare services, the contextural landscape is one of a decreasing labor market, higher demands for quality of care voiced by baby boomers, and uncertainty of incomes of older people. (3, 4) Approximately 10% of all Dutch elderly over the age of 75 live in residential care homes. (5, 6) Of this population, over 70% require professional assistance with activities of daily living, nursing care and housekeeping. (5, 6) There are approximately 100 residents per residential care home. (3) When senior citizens enter into a residential care home, they keep their family physician if possible. There is a trend to keep the elderly in their own homes for as long as possible to maximize their level of independence as well as it can be less expensive from a governmental perspective. (7, 8) As a consequence, the residential care home population resembles nursing home populations more and more. (9-12) Residential care homes were not designed to address these populations and family physicians are challenged by these complex patients. (9, 13, 14) Most care organizations want to innovate and improve their quality of care but lack expertise or financial resources. (9, 13, 15) The Multidisciplinary Integrated Care approach is inspired by the chronic care model (Bodenheimer et al (16), Wagner et al (17)) and may improve quality of care (Boorsma et al., 2008). The objective of this study was to determine the cost-effectiveness of the multidisciplinary care approach compared to usual care in a sample of 10 residential care homes in the Netherlands. In an earlier paper, it was found that this approach resulted in significantly higher quality of care. (18)

METHODOLOGY

DESIGN AND SETTING A clustered, randomized controlled trial with 6 month follow-up was conducted in 10 Dutch residential care homes. (9) Residential care homes were randomized to either the intervention or control group resulting in each arm of the trial including 5 residential care homes. A detailed description of the design was published elsewhere. (9, 18) The ethical committee of the VU Medical Centre approved the study.

RESIDENT SELECTION Patients were recruited from December 2006 until December 2007. All residents within the 10 residential care homes were invited to participate in the clinical trial. A resident was excluded from the study if he/she was viewed by the staff or primary care physician as too terminally ill to complete the study (9). All participants or their representative signed informed consent.

THE USUAL CARE MODEL A residential care home is a retirement home for seniors who can no longer live independently. (19) Residential care homes typically offer general care such as; domestic help, leisure activities and meals for all occupants or a large portion of the occupants. (19) Ad hoc nursing care for individual occupants is also possible. Many of these residential care homes have merged with nursing homes which have resulted in organizations with a wide variety of services. No new interventions were introduced into this arm of the study. Care providers were instructed to continue the care to the residents that they would normally provide.

THE MULTIDISCIPLINARY INTEGRATED CARE APPROACH The intervention of the multidisciplinary integrated care approach consists of three steps as explained in Boorsma et al. (9) Firstly, a quarterly in-home systematic and computerized multidimensional assessment of all residents by trained nurse-assistants systematically reviewed the functional health status and care needs using the InterRAI-LTCF which is a comprehensive, standardized instrument for evaluating the needs, strengths, and preferences of those in chronic care and nursing home institutional settings. (20) The InterRAI-LTCF assessment form incorporates domains such as; function, mental and physical health, social support, medication and service use. (20) The problem areas identified become the foundation for the individual care plan. (20) Secondly, the outcomes of the assessment were discussed in a multidisciplinary meeting in the homes with the family physician, elderly care physician, nurse-assistant, psychogologist and other involved disciplines. Lastly, a multidisciplinary consultation was offered to the frailest residents with complex health care problems which were identified by the level of expected resource utilization. (9, 21)

CLINICAL OUTCOME MEASURES

A weighted 32 item sum score was created to determine patient level quality of care. (18) The quality indicators were based on observations recorded in the interRAI-LTCF assessment form. (22) During the study independent trained interviewers collected these observations at baseline and after 6 months. The lower the sum score, the higher the quality of care. Functional health, an important aspect of quality of life, was measured by COOP WONCA charts. (23) Higher scores are indicative of better functional health. The 12- Item Short Form health survey (SF12) was used to measure general quality of life. Based on the SF12 data, Quality Adjusted Life Years (QALY) were calculated using utility scores estimated by the SF6D tariff. (24) Transitions between health states were linearly interpolated.

COST OUTCOME MEASURES

Cost data were collected at baseline and six months from a societal perspective. Health care utilization data were collected by patient or proxy interview and medical records at baseline and at six months. (9) Table 1 lists the cost categories and prices used in the economic evaluation. All prices were adjusted for the year 2007 using consumer price index figures. (25) Costs of medications were valued using prices from the Royal Dutch Society for Pharmacy. (26) A cost price for the multidisciplinary integrated care approach was calculated using a top down approach. Total costs included: organizational costs, training costs, InterRAI costs and multidisciplinary meeting costs (see Table 1). Costs were calculated on an annual basis and then proportioned for the six month trial. Total costs of the intervention were divided by the total number of residents living in the intervention residential homes. Multidisciplinary meetings are part of usual care by law. However, in daily practice, not all homes hold these meetings on a regular basis. We also calculated costs for the meetings held in the usual care home. In a sensitivity analysis, only the license costs of the InterRAI and the InterRAI subscription costs per patient were included.

STATISTICAL ANALYSIS

Data was analyzed according to the intention to treat principle. However, patients who died during the study were excluded from the analyses. The multiple imputation function in SPSS-18 was used to predict missing values for cost and effect data. This function created five imputed data sets that were pooled together using Rubin’s rules. (27) Individual cost components were imputed at a patient level instead of overall total cost per patient to minimize unnecessary deletion of information. As patient-level cost data have a highly skewed distribution, bootstrapping was performed with 5000 replications to estimate Approximate Bootstrap Confidence (ABC) intervals around cost differences. (28, 29) Incremental cost-effectiveness ratios (ICERs) were calculated by dividing the difference in total costs between multidisciplinary integrated care and usual care by the difference in clinical effects. Non-parametric bootstrapping was also used to estimate the uncertainty surrounding the ICERs (5000 replications). The bootstrapped cost-effect pairs were plotted on a cost-effectiveness plane (CE plane) (30) and used to estimate cost-effectiveness acceptability curves (CEA curves). CEA curves illustrate the probability that the intervention is cost-effective in comparison with the control treatment for a range of ceiling ratios. The ceiling ratio is defined as the societal willingness to pay in order to gain one unit of effect. (31) Two sensitivity analyses were performed. One included only the complete cases and the second one included only the licensing and subscription costs of the interRAI as described above.

RESULTS

From December 2006 until December 2007, a total of 462 residents were requested to participate in the trial. Randomization was carried out at facility level. At baseline, 340 people were interviewed (201 intervention patients and 139 control patients). There were no significant differences in patient characteristics between the two groups at baseline (Table 2). A total of 33 people died (15 (11%) control and 18 (9%) intervention patients) before the six month follow up. Complete clinical outcome data was available for 147 patients (72%) in the intervention group and 87 (60%) patients in the control group. Selectively missing data was found as the participants that dropped out were approximately two years older (95% CI 0.42 ; 3.66) and had better activities of daily living score as measured by the Groningen Activity Restriction Scale (GARS) compared to completers (mean difference -3.4; 95% CI -6.7 ; -0.1).

**CLINICAL EFFECTIVENESS** Quality of care was significantly higher in the intervention group than the control group (mean difference -6.5, 95% CI -9.5 ; -3.5). There was no statistically significant difference in effect for either of the other outcome measures (Table 3).

**COSTS** Costs of the intervention amounted to €225. There was a trend that total costs were higher in the intervention group compared to UC by €404 (95% CI -13 ; 826, Table 4). Direct healthcare costs were the largest contributor to total costs in both groups. The highest cost driver within direct healthcare costs for both groups was secondary care costs such as hospital admission (Table 4).

*Implementation costs consist of the MIC costs in the intervention group and of the costs of the multi-disciplinary meetings in the control group.

**COST-EFFECTIVENESS ANALYSIS**

Quality Indicators The sum score of quality of care resulted in a negative ICER of 62, indicating that for every one point improvement on the sum score, the multidisciplinary integrated care approach costs €62 compared to usual care. Figures 1 and 2 show the CE plane and CEA curve. The majority of the cost-effectiveness pairs (97%) were in the northeast quadrant suggesting that the intervention is significantly more effective and more costly than usual care. The CEA curve showed that the investment needed to reach a 0.95 probability that multidisciplinary integrated care was cost-effective compared to usual care was €129 or more.

**COOP WONCA** The ICER for the COOP WONCA was 2,056 meaning that 1 point improvement in COOP WONCA score costs €2,056 for multidisciplinary integrated care versus usual care. The majority (97%) of the cost-effect pairs fell in the Northern quadrants of the CEA plane indicating that total costs in the multidisciplinary integrated care group are higher compared to the usual care group while there is a statistically non-significant difference in effects. The CEA curve showed that the maximum probability that multidi-
Multidisciplinary integrated care was cost-effective compared to usual care was 0.6. However, to reach this probability the societal willingness to pay should be approximately €5,000 per patient.

QALY The ICER for QALY scores was -248,308 indicating the multidisciplinary integrated care had higher costs and negative effects compared to usual care. Figures 3 and 4 show the CE plane and CEA curve. Most (63%) bootstrapped cost effect pairs were contained in the Northwest quadrant meaning that multidisciplinary integrated care was less effective and more costly than usual care. The CEA curve presented in Figure 4 shows that the maximum probability that multidisciplinary integrated care is cost-effective in comparison with usual care was 0.14. However, decision makers should be willing to invest huge amounts of money to reach this probability.

Figure 3

![Image](86x31 to 305x234)

Incremental costs pooled dataset

Figure 4

![Image](86x242 to 352x500)

Incremental effects pooled datasets

Sensitivity analysis The results of the clinical outcomes in the complete case analysis were consistent with those of the imputation analysis. Total costs were higher in the intervention group than in the control group but not statistically significantly which is consistent with the imputed analysis. Although the conclusion for the cost effectiveness analysis was the same for both the imputed and complete case analysis the numbers varied (data not shown). The second sensitivity analysis including only licensing and subscription costs for interRAI-LTCF showed that total costs were not significantly different between the intervention and the control group.

INTERPRETATION

SUMMARY An economic evaluation was performed to determine whether multidisciplinary integrated care was cost-effective compared to usual care. General scales of functional health did not significantly differ between the groups at six month although quality of care was significantly higher in the intervention group. There was a trend that total costs were higher in the intervention group than usual care. For functional health and QALYs we concluded that multidisciplinary integrated care was not cost-effective compared to usual care. Whether multidisciplinary integrated care is considered cost-effective in comparison with usual care for quality of care depends on the amount of money decision makers are willing to additionally spend on care for this group of elderly nursing home residents. Conclusions were similar in the complete case analysis.

EXPLANATION OF THE FINDINGS This raises the question why was quality of care higher in the intervention homes compared to the control homes? It is possible the quality indicators in the control homes did not improve to the same extent as in the intervention homes because intervention participants were receiving increased attention from the residential home staff as well as increased referrals to secondary care. The increase in secondary care may have induced the need for the informal caregiver to attend and help transport patients to the secondary care appointments which may explain the increased informal care costs. If there was unmet care, then the use of the interRAI-LTCF and the multidisciplinary meetings addressed this gap in care. However, a trade-off needs to be made whether the additional effects are worth the additional costs.

EXISTING LITERATURE COMPARISON Previous studies suggest interRAI has positive effects on health outcomes in nursing facilities as well as in residential homes. (32, 33) However, there were criticisms on the study designs and the conclusions drawn indicating a need for better designed trials. (34) A four month trial from New Zealand estimated health care services utilized and the cost of implementing the minimum data set home care assessment compared with usual care. (35) They found that the interRAI was significantly more costly in prescribed and delivered services compared to usual care but the author believed that the cost differences may be due to a genuine need of services for this population. (35) We think that our trial is an important addition to the knowledge base on the effect of the interRAI in clinical care.

LIMITATIONS The six month follow-up may not have been enough to capture all potential costs and effects. Patients in a residential home have a heterogeneous mix of chronic conditions that naturally erode health over time which makes it difficult to know if an intervention of this sort would be able to override the downward trend of health states associated with chronic conditions in such a short time span. The primary outcome variables may not have been sensitive enough to pick up differences within such a limited time interval. Another limitation was the considerable amount of missing data. In this
study, non-completers tended to be older and had better activities of daily living scores. As the intervention really targeted only the frailest it could be that they did not feel like they were benefitting enough from the study intervention. In situations where there are missing costs, multiple imputation is recommended which was also performed in this study.

CONCLUSION This study showed benefit on quality of care, against a modest cost increase. Longer term follow up of costs and effects is needed to further substantiate the findings. Future research should consider the reasons why it did not translate over to the other clinical outcome variables. Its pragmatic study design resembles clinical practice to a high degree which increases the relevance of the study results.

ABSTRACT

BACKGROUND Prerequisites of successful introduction versus maintenance of care innovations are not well understood and may depend on interplay of contextual issues such as type of care setting, type of innovation, and personal involvement. In this study the facilitating and impeding factors were studied of both initial and maintaining implementation of a multidisciplinary integrated care approach comprising monitoring and decision support with the inter RAI Long Term Care Facility Instrument (inter RAI-LTCF ) in ten Dutch residential care homes aimed to improve quality of care.

METHODS Facilitating and impeding factors were studied and compared at the time of introduction of the inter RAI-LTCF in residential care homes as well as three years later, by surveys and semi structured interviews among nurse staff, managers, and physicians.

RESULTS Facilitating factors at introduction were positive opinions of staff and family physicians about the changes of the process of care and the anticipated improvement of quality of care. Staff was positive about the applicability of the software to support the inter RAI-LTCF assessments. Impeding factors were time constraints to complete inter RAI-LTCF assessments and insufficient computer equipment. In the maintenance phase, the positive attitude of the manager and the perceived benefits of the care model were most important. Impeding factors after 3 years remained the lack of time to complete the assessments and lack of sufficient computer equipment.

CONCLUSIONS Impeding and facilitating factors were comparable in the initial and maintenance phase. Adoption of the inter RAI-LTCF assessment method depended on positive opinions of staff and management, continuing support of staff (predominantly in time, training and coaching) and the availability of sufficient computer equipment.
INTRODUCTION

Quality of care for elderly in residential care homes is under pressure in the Netherlands as in other countries. Facilities tend to be understaffed and the care complexity of residents increases while expertise of staff does not keep pace. (17) Although most care organizations want to innovate and improve their quality of care, many lack the expertise or financial resources to do so. (7,8) Family physicians are responsible for the medical care in Dutch residential care homes but do not regard themselves suited for systematic management and long-term monitoring of chronic diseases and disabilities associated with frail health. (6) These conditions were the ingredients for the development and implementation of a new care model in a north-west region of the Netherlands. This new care approach was inspired by the Chronic Care Model of Wagner and Bodenheimer. (4) The effects of this innovation were studied in a Randomised Controlled Clinical Trial design in ten Dutch residential care homes (Boorsma et al 2011). This multidisciplinary integrated care approach demands changes at all levels of an organisation and consists of: (1) repeated structural computerised multidimensional geriatric observations by trained staff, (2) patient tailored care plans based on the outcome of the observations (3) multidisciplinary consultations including nurse staff, family physicians, elderly care physicians and psychologists, (4) quarterly benchmark reports on 32 quality of care indicators. The assessment instrument used in this care model was the web based Long Term Care Facility version of inter RAI (inter RAI-LTCF). Prerequisites of successful introduction versus maintenance of care innovations are not well understood. Reviews of dissemination and implementation strategies suggest that success depends on the type of care setting, type of intervention and specific circumstances. (10) People working in healthcare organizations mostly focus on their own profession. This professional identification limits the level of organizational identification; the willingness to collaborate across specializations or departments, which is imperative when organizations want to work on improvements and innovation. (15;16) A review by Grimshaw et al. (1999) showed that obstacles to use guidelines can arise at different levels of the health care system: at the level of the patients, the individual professional, the health care team, the health care organization or the wider environment. (11,12) The introduction of an assessment instrument like the inter RAI-LTCF had consequences for the care process at all of these different levels. We were able to study these consequences on the level of the individual professional, the health care team and health care organization (management residential care homes). Often not only the introduction (initial phase) but also the maintenance is under pressure in health organisations due to shifting priorities, lack of time and money needed for ongoing and renewed training and equipment. (3) Therefore we studied both moments in time.

The research questions that are addressed in this paper are:
1. Which factors facilitate or impede the introduction of the inter RAI-LTCF as part of the Multidisciplinary Integrated Care model in residential care homes?
2. Which factors facilitate or impede the use of the inter RAI-LTCF in the maintenance phase, three years after introduction.

METHODS

In this study a mix of quantitative and qualitative methods was used. During the initial phase of the implementation, the opinions and experiences of all home managers, nurse assistants and family physicians were collected in surveys and semi structured interviews. These interviews and surveys were held in 5 residential care homes that participated in a cluster randomized clinical trial and allocated to the intervention group. These homes started working with the inter RAI-LTCF according to the multidisciplinary integrated care model. Boorsma et al. 2011 described the design and outcome of this trial on quality of care and quality of life. (Boorsma et al CAMJ in press) During the maintenance phase, three years after the initial implementation, we selected 3 out of 10 participating homes on different scores of quality of care performance according to quarterly benchmark reports based on the VU RAI database. We selected the best, the lowest scoring home and one average scoring home compared to the benchmark. From these three homes the managers (n = 3) and two staff members were interviewed (n = 6). The staff members were nurse-assistants who work daily with the inter RAI-LTCF and coordinate care planning of individual residents.

MULTIDISCIPLINARY INTEGRATED CARE MODEL

The Multidisciplinary Integrated Care model was inspired by the chronic care model and comprises 4 elements. First an assessment with inter RAI-LTCF of the patient’s functional health and care needs is imperative. This enabled immediate identification of problem areas which supports individualised care planning. Secondly, the assessment outcomes were discussed in a Multidisciplinary Meeting (MM) with the nurse assistant, family physician, elderly care physician and psychologist. The Multidisciplinary Meeting (MM) provided advice on management and treatment of modifiable disabilities and risk factors. Thirdly, consultation by elderly care physician and psychologist was offered to the frailst residents at risk for nursing home admission. Finally, a quarterly benchmark report compared 32 risk adjusted indicators of quality of care across all residential and nursing homes in the Netherlands that used the inter RAI-LTCF. (9;18) Management can use this overview to improve specific areas of care. For example, if the (case mix adjusted) number of falls is substantially higher compared to the expected average (benchmark), management can decide on measures to improve safety in a particular home. The Association of RAI users in the Netherlands, Nedrai, owns the software, and provides these overviews for a limited tariff per resident (www.nedrai.nl).

THE INITIAL PHASE OF THE INTERVENTION

On instigation of the family physicians of the residents, the management board of the residential care homes agreed to initiate a care improvement project in their homes. In the initial phase 45 nurse-assistants, five team coaches and managers of five residential care homes were trained in a two day course by external trainers. In this course the background and position of the assessment instrument in the multidisciplinary integrated care approach was explained and the use of the web based version of the inter RAI-LTCF was practiced. Special attention was given to designing individualized care-plans based on the assessments and in sharing this information with the residents or their relatives and other professionals like the family physician. The care organisation appointed a project leader during the implementation for two days a week. A steering committee was installed that initially met two weekly and less frequently as the project enrolled. In the maintenance phase new staff received in company training as sufficient experience was gained within the organisation.

MEASUREMENTS AND DATA ANALYSES

For research question 1 Semi-structured interviews were held in the initial phase of the introduction of inter RAI-LTCF with nurse-assistants, team coaches and managers of the intervention homes randomised in the randomised clinical trial study. In addition, a brief questionnaire was send to the family physicians who were involved. The interview and the questionnaire were composed based on literature review, expert opinion and piloted before the data collection. The questions were covered subjects like: training aspects, autonomy and self guidance for staff, time investment and applicability of inter RAI-LTCF, quality of care, and communication between family physicians and staff. Those interviews were held and analysed by one researcher and supervised by two other researchers. The answers of the questionnaire are presented in percentages (table 1,2).
For research question 2 The information and data of the maintenance phase was collected through in-depth interviews with three home managers and six nurse assistants who used the instrument. The focus of these interviews was to elicit opinions on the instrument and its use in real-life work. The managers were chosen to be interviewed because of the overview they have in the homes and the possible usefulness of the inter RAI-LTCF according to their perspective. From each of the facilities two staff members were interviewed. These staff members were nurse assistants who worked on a daily basis with the inter RAI-LTCF. To obtain sufficient background information several interviews were held with the two project managers initially responsible for the implementation of inter RAI-LTCF in the homes. During the interviews, the conversations were taped and described verbatim afterwards. During the analysis these notes have been re-read and the conversations re-listened to make sure all was noted well. (14) The data collected in the interviews was displayed in tables. Quotations were used to show explicit opinions and feelings that were present among the interviewees.

RESULTS

THE INITIAL PHASE Seventeen nursing assistants, five team coaches, and three managers of five residential care homes as well as 14 family physicians were interviewed. The average size of the homes was 46 residents. The average ratio nurse-assistant to residents was 1 to 15. Staff was predominantly female (88.2%) had a mean age of 41.4 years, and the majority (64.7%) completed an education of nursing assistant and 17.6% of nurse. They had a mean job experience of 17.9 years and the average work hours a week was 28.4 (SD 4.4). Application of the Multidisciplinary Integrated Care model Assessment: 55.2% percent of the residents in the five intervention homes was assessed with inter RAI-LTCF during the study period of 6 months. This was less than what was aimed for and was partly due to implementation delays. For example, one intervention home actually started RAI assessments 3 months after the start of the study period. The instrument. The focus of these interviews was to elicit opinions on the instrument and its use in real-life work. The managers were chosen to be interviewed because of the overview they have in the homes and the possible usefulness of the inter RAI-LTCF according to their perspective. From each of the facilities two staff members were interviewed. These staff members were nurse assistants who worked on a daily basis with the inter RAI-LTCF. To obtain sufficient background information several interviews were held with the two project managers initially responsible for the implementation of inter RAI-LTCF in the homes. During the interviews, the conversations were taped and described verbatim afterwards. During the analysis these notes have been re-read and the conversations re-listened to make sure all was noted well. (14) The data collected in the interviews was displayed in tables. Quotations were used to show explicit opinions and feelings that were present among the interviewees.

The majority (82.4%) of the nurse-assistants was satisfied with the inter RAI-LTCF and 58.8% considered the individual parts of the instrument as obvious. About the training itself, 47.1% was satisfied. But the same percentage of nurse-assistants asked for more explanation about the usefulness of the tool. Staff was also satisfied with the applicability of the software to support the inter RAI-LTCF assessments (71%). About 55% of the family physicians (n = 14) considered the quality of care to be improved. They acknowledged that there was a need for a new care model (73%). Of the nurse assistants 52.9% had the opinion that their competence had increased with the application of inter RAI-LTCF but only 35.3% considers the quality of care improved. The managers were divided on this point. They say that the use of inter RAI-LTCF introduced uniformity and the possibility of quality control.

IMPEDE FACTORS Many nurse-assistants said that they did not receive enough time to fill in the inter RAI-LTCF and managers confirmed this. Other impeding factors mentioned by the nurse-assistants were not enough computers (47.1%) and insufficient capacity of these computers (64.7%).

THE MAINTENANCE PHASE All residential care homes used inter RAI-LTCF assessments for their residents (n = 322) every 6 months and extra in case of important changes in client situation. In 2008 the inter RAI-LTCF was implemented in the best and the average performing home, and in 2007 in the lowest scoring home. The latter home had faced problems like frequent change of management and lack of nursing staff which led to neglect of the use of inter RAI-LTCF. (Table 3-8)

Resistance to change

Staff in all three studied facilities still tended to have resistance against working with the inter RAI-LTCF. Only in home Nr 3 (the lowest scoring home) staff was less resistant. Management in all three studied facilities described that they tried to reduce this resistance by emphasizing the usefulness of this new assessment system and involving staff by taking courses in the use of the inter RAI-LTCF.

Facilitating factors after 3 years

After 3 years most nurse-assistants recognise that using the instrument improved communication with colleagues and other disciplines like the family physicians and elderly care physicians. Nurse-assistants do mention that they have a better overview of the health problems of the residents with the use of the inter RAI-LTCF. Most of them agree on the improvement of the quality of the Multidisciplinary Meetings.

Impeding factors after 3 years

Impeding factors also after 3 years were the lack of time and sufficient good working computers. Some nurse-assistants claimed that the benefits of the inter RAI-LTCF are not clear to them. Overall, in content and quantity the nurse-assistants of residential care home Nr 2 are the least positive about the use of the inter RAI-LTCF. Remarkably, nurse-assistants of the lowest scoring residential care home saw the least drawbacks and the most benefits of the RAI-LTCF. This is somewhat contradictory to the finding that they had the lowest score compared to the other two homes on the quality of care outcome report. It may be explained by the fact that this home had serious troubles with management. The manager that took over was very positive about the instrument and the care model.

Conclusions

The main conclusion of this study is that the facilitating and impeding factors in the initial phase as well as in the continuing phase were comparable. Facilitating factors as positive opinions and support of managers is in both phases of great importance. Pointing out the benefits of the new care approach with the use of a time consuming assessment is an important factor for staff in the initial phase. These benefits of the assessment tool for nurse-assistants are a better understanding of the clients’ problems, enabling them to go beyond merely executing physicians’ orders and to become active players in planning clients’ care. The impeding factors as shortage of time and insufficient equipment were found in both phases and do frustrate the process.

Comparison with literature

Bernabei et al. (1995) implemented a comparable care model for community dwelling elderly and used the Home Care version of the Resident Assessment Instrument (RAI-HC). They called the implementation a revolution similar to the modifications seen in industry when a new technology is introduced and the traditional process of production is changed. It is not by chance that some have defined comprehensive geriatric assessment as the “technology” of geriatrics. Because it is more complex than traditional tools, and probably also because, in Italy, like in our (Dutch) situation the assessment instrument was being used by people who had no previous knowledge of this kind of technology, the RAI-HC produced true innovation. This innovation also changed the relationships between professionals like family physicians, elderly care physicians and nurse-assistants. In comparison with Bernabei (6 days course), Holtkamp (4 days course) and Achterberg (4 days course) our training session was relatively short (2 days course) and almost half of the nurse assistants wanted more information. The implementation also altered the role of the nursing assistant to a more proactive communicating professional. Like Bernabei we also found resistance likely due to the ignorance of the rationale of the multidimensional assessments by people working in geriatric care. Various professionals like the elderly care physician, psychologist and some nurse-assistants had a hard time accepting the rationale of such an assessment tool and system. Other impeding factors like staffing problems and inadequate equipment were also found by Holtkamp (2003) and Achterberg (2004).

Strengths and limitations

We were able to achieve participation from a large and extremely difficult study population and implemented a multidisciplinary integrated care approach in a single care organization having the possibility of uniform implementation. This contributed greatly to the internal validity of the study results. There are some limitations. For the first research question the investigated sample was limited due to lack of time, illness and vacation of managers and nurse assistants. In addition, the interviews used in the initial phase were tested on construct and expert validity but not on criterion validity and reproducibility. For the second research question an important limitation was the relatively small sample which was due to the exploratory and in-depth nature of the interviews. Another possible limitation is that this study was conducted in three residential care homes all belonging to the same care organization. Because of the small sample and the exploratory nature of the research all generalizations are merely indications.

Practical implications

Although the benefits seem to overrule the drawbacks, implementing the use of an assessment tool like the inter RAI-LTCF is not an easy process. Successful implementation in daily routine depends on sufficient training and coaching of professionals, sufficient equipment and sustaining support of management.

DEPRESSION IN DUTCH RESIDENTIAL CARE HOMES: UNDER-DIAGNOSES IN DEMENTED RESIDENTS?

CHAPTER 7

Although community-based studies reported an increased incidence of depression among demented persons compared with non-demented persons, it is not clear whether this relationship also exists among institutionalised elderly persons. The aim of this study was to compare the prevalence of diagnosed depressive disorders and mood symptoms between demented and non-demented residents living in Dutch residential care homes.

METHODS Cross-sectional analysis in 16 residential care homes of routine outcome measurements by trained nurse assistants using the Resident Assessment Instrument (RAI) between January 2007 and April 2008. Nurse assistants recorded all known medical diagnoses including dementia and depression, as well as a structured observation of the presence or absence of 11 mood symptoms over the last three days.

RESULTS 313 demented and 463 non-demented residents with complete data were included (99% of all residents, mean age 84 years). 24.6% of participants were diagnosed with a depressive disorder, with no statistically significant difference between demented and non-demented persons (p=0.237). Mood symptoms were more prevalent in demented residents (p<0.001, OR 2.14, 95%CI 1.56-2.93). Among residents with mood symptoms, demented residents were less likely to be diagnosed with a depressive disorder than non-demented residents (p=0.039, OR 0.61, 95%CI 0.38-0.98).

CONCLUSIONS The prevalence of diagnosed depressive disorders was comparable between demented and non-demented residents. However, demented residents suffered more from mood symptoms and may be at risk of under-diagnosis of depression.
INTRODUCTION

Depressive symptoms and disorders are highly prevalent in residents of residential care homes. (1-9,14-18,20-25) Since the prognosis of depression in residents is poor, including low recovery and higher mortality rate, depressive disorders and symptoms constitute a serious health problem. (12,19,25) Although community-based studies reported a higher prevalence of depression in persons with dementia or cognitive decline than in non-demented or cognitively unimpaired elderly people, it is not clear whether this is also the case in residential care homes. (3,10,24) To our knowledge, only two studies compared demented and non-demented residents on prevalence of depressive symptoms or disorders. (7,14) In an Australian study, major depressive disorders were more prevalent among cognitively impaired residents (27.5%) compared to cognitively unimpaired residents (15.5%). (7) In a Dutch study, no statistically significant difference was found in the prevalence of depressive syndromes and symptoms between demented and non-demented residents. (14) Both studies were hampered by non-response and exclusion of residents, as a result of which only 72% and 33% respectively of the source population was included. (7,14) This could have biased the comparisons between demented and non-demented residents. In our study, we had access to medical data, including validated assessments. These routine care outcome measurements provide complete and reliable prevalence estimates of diagnosed depressive disorders and symptom observations, since virtually all residents are included. The aim of this study was to compare the prevalence of diagnosed depressive disorders and observed mood symptoms between residents with and without dementia in Dutch residential care homes.

METHODS

DESIGN AND SETTINGS

This cross-sectional analysis was performed on data collected on 787 residents in 16 residential care homes in the Netherlands. These homes were situated in rural as well as urbanised regions of the country and varied in number of residents (mean 54, SD 35). The residents of these homes are vulnerable elderly persons who need assistance with activities of daily living (ADL), supervision or require sheltered living. In contrast to nursing homes, residential care homes provide neither specialised medical care nor nursing care. The family physician is responsible for the medical care in a residential care home. Informed consent was not required as the data concerned anonymous routine care data.

DATA COLLECTION

This cross-sectional analysis was performed on data collected on 787 residents in 16 residential care homes in the Netherlands. These homes were situated in rural as well as urbanised regions of the country and varied in number of residents (mean 54, SD 35). The residents of these homes are vulnerable elderly persons who need assistance with activities of daily living (ADL), supervision or require sheltered living. In contrast to nursing homes, residential care homes provide neither specialised medical care nor nursing care. The family physician is responsible for the medical care in a residential care home. Informed consent was not required as the data concerned anonymous routine care data.

DEPRESSIVE DISORDER

In the disease diagnosis part of the inter RAI-LTCF, all present medical diagnoses relevant for the personal care plan were registered. These diagnoses were made by a family physician or medical specialist. All Dutch clinical guidelines for depression refer to DSM-IV criteria to make diagnoses. The recorded diseases reflected the awareness of medical diagnoses based on the usual care process. Medical diagnoses remain recorded in the inter RAI-LTCF until a physician indicates that the resident has recovered. Compared to standardised testing, routine care registration of depressive disorders is accurate in severe cases but tends to under-diagnose in cases with mild to moderate severity.

DEMENTIA

Dementia was also recorded as a medical diagnosis in the inter RAI-LTCF. Dementia diagnoses were made mostly by a geriatrician or memory clinic. All Dutch clinical guidelines for dementia refer to DSM-IV criteria to make diagnoses. Staff in the residential care homes were keen to instigate dementia diagnostics when signs were present, because the homes received a higher tariff for demented residents. Therefore under-diagnosis of dementia is likely to be limited.

MOOD SYMPTOMS

The mood and behaviour section of the inter RAI-LTCF contains 11 items on mood, with regard to which observations are made by trained staff (Table 3). The scores per item vary between 0 (not present), 1 (present but not in the last 3 days), 2 (present on 1 or 2 days of the last 3 days) and 3 (present daily in the last 3 days). The 11 items on mood, including the key symptoms of the DSM-IV depression criteria, reflect observed behaviour interpreted here as depressive symptoms (Cronbach’s alpha 0.84). Frequencies on individual items are presented in Table 3. We decided to use the sum score of all 11 items on mood instead of the seven items that comprise the validated Depression Rating Scale (DRS), since substantial changes in the ratings of the inter RAI-LTCF have made the DRS based on the old RAI-LTCF version unsuitable. Moreover, at least two studies reported a limited correlation of the DRS with the self-reported Geriatric Depression Scale and the psychiatrist-rated Hamilton Depression Rating Scale.

STATISTICAL ANALYSIS

All analyses were done using SPSS 14.0. To carry out the analyses on mood symptoms, the sum score of the 11 mood items was dichotomised on the mean, with the result that residents with a sum score of 6 and higher were compared with those having less mood symptoms (sum score ≤ 5). Prevalence of diagnosed depressive disorders and dementia was calculated using descriptive statistics. P-values for differences between demented and non-demented residents were determined with 2-tailed Pearson Chi-Square tests, in which p-values < 0.05 were considered as statistically significant. Univariate regression analysis was used to calculate the odds ratio and 95% confidence interval for associations with dementia as the independent variable and diagnosed depressive disorders and mood symptoms as the dependent variables. This method was also used for the relation between dementia and diagnosed depressive disorders in the subgroup of residents with a sum score of 6 and higher on the 11 mood items. Furthermore, multivariate regression analyses were carried out to explore the presence of confounders of these relationships. Co-variables that changed the odds of a univariate association by 10% or more were considered a confounder and were added in the multivariate analyses to adjust the primary odds ratios. Subgroup effects were explored by interaction analyses. For example, modification of the main association between dementia and depressive disorders by social engagement was explored by adding the interaction term social engagement x dementia. When a statistically significant interaction term was found, the study population was split to demonstrate...
the results for the subgroups (high versus low social engagement) separately. The following variables recorded in the inter RAI-LTCF were explored as potential confounders and effect modifiers for each relationship under study. Continuous variables were dichotomised on the mean to generate comprehensible odds ratio’s.

- Gender: men versus women.
- Age: 0-84 versus 85 and older.
- Pain symptoms: 0-2 versus 3-11, sum score of 4 items on frequency, intensity, duration and occurrences of pain. Internal consistency expressed in Crohnbach’s alpha was 0.86. The higher the sum score, the more pain was observed.
- ADL-dependency: 0-17 versus 18-54, sum score of 9 items on help needed for activities of daily living (Crohnbach’s alpha 0.95). The higher the sum score, the higher the dependency.
- Somatic symptoms: 0-10 versus 11-87, sum score of 22 items on frequency of health problems, dyspnoea and tiredness (Crohnbach’s alpha 0.69). The higher the sum score, the more somatic symptoms were observed.
- Social engagement: 0-10 versus 11-18, sum score of 6 items on feelings of social engagement (Crohnbach’s alpha 0.89). The higher the sum score, the better the social engagement.
- Number of diseases, except dementia and depressive disorder: 0-1 versus 2-63.
- Diabetes mellitus: yes versus no.
- Recent infections, including pneumonia and urinary tract infection in last 30 days: yes versus no.
- Cardiovascular disease, including cerebrovascular accident, coronary disease, chronic heart failure, vascular diseases, cardiac arrhythmia, hypertension, heart diseases, decompensatio cordis and cerebrovascular diseases: yes versus no.

RESULTS

POPULATION The source population of this study consisted of 787 residents of residential care homes, and 776 cases had complete data on the variables of interest (99%). These 776 persons were included in the analyses and comprised 313 demented and 463 non-demented residents. The mean portion of demented residents was 40.3%, which varied between 18.6% and 76.9% across the 16 residential care homes. Demographic characteristics of the residents are shown in table 1.

PREVALENCE OF DIAGNOSED DEPRESSIVE DISORDERS Table 2 shows the prevalence of diagnosed depressive disorders and mood symptoms. 24.6% of all residents were diagnosed with a depressive disorder. No difference was found between demented and non-demented residents (p = 0.237). Adjusted for the only confounder, ADL, the odds ratio (= OR) for the relation between a diagnosis of dementia and diagnosed depressive disorder in the total population was 1.06, with a 95% confidence interval (= CI) of 0.75-1.49. Social engagement modified this relationship: depression was more often diagnosed among highly socially engaged demented persons (OR 1.85, 95%CI 1.15-2.97), while there was no difference between demented and non-demented residents with low social engagement (OR 0.77, 95%CI 0.48-1.23).

PREVALENCE OF OBSERVED MOOD SYMPTOMS Table 3 shows the prevalence of 11 separately observed signs of depressed mood. The score 1 (present, but not in the last 3 days), 2 (present on 1 or 2 of the last 3 days) and 3 (present daily in the last 3 days) on these items were taken into account. 13.7% of the demented and 37.6% of the non-demented residents showed none of the observed symptoms, whereas in 59.1% of the demented and 39.3% of the non-demented residents three or more symptoms were observed. In demented residents, the signs of ‘persistent anger with self or others’ and ‘reduced social interaction’ were most prevalent (48.6%). However, the sign of ‘sad, painful or worried facial expressions’ was most prevalent in non-demented residents (36.1%). The sign ‘recurrent statements that something terrible is about to happen’ was observed least in both
groups (5.1% of the demented and 6.7% of the non-demented residents). Remarkably, 7 of the 11 items were observed significantly more frequently in demented residents than in non-demented residents. Using the cut-off point of 6 or higher of the sum score on the 11 observed items, 36.9% of the residents suffered from observed mood symptoms. There was a substantial and statistically significant difference between demented (50.5%) and non-demented (27.6%) residents (p < 0.001). After adjusting for the confounder ADL, the odds ratio was 2.14 (95% CI 1.56-2.93). Diabetes mellitus was an effect modifier for this relationship. In the subgroup of residents with diabetes mellitus, there was no statistically significant difference in the prevalence of mood symptoms between demented and non-demented residents (OR 1.02, 95% CI 0.54-1.91). Among persons without diabetes mellitus, demented residents showed more mood symptoms than non-demented residents (OR 2.74, 95% CI 1.90-3.95).

RELATION BETWEEN MOOD SYMPTOMS AND DIAGNOSED DEPRESSIVE DISORDER

40.2% of the residents who showed mood symptoms were diagnosed with a depressive disorder, with a significant difference between demented (34.8%) and non-demented (46.9%) residents (p = 0.039). Among persons with mood symptoms, demented residents were less likely to be diagnosed for having a depressive disorder than non-demented residents, OR 0.61 (95% CI 0.38-0.98). No confounders or effect modifiers were found for this relationship.

DISCUSSION

MAIN FINDINGS

This cross-sectional study compared the prevalence of diagnosed depressive disorders and observed mood symptoms between demented and non-demented residents of Dutch residential care homes. No statistically significant difference was found between demented and non-demented residents in the prevalence of diagnosed depressive disorders. However, observed mood symptoms were more prevalent in persons with dementia than in people without dementia. Among persons with mood-symptoms, demented residents were less likely to be diagnosed with a depressive disorder than non-demented residents.

IMPLICATIONS

The higher prevalence of mood symptoms in demented residents compared with non-demented residents can be explained in at least two ways. One possibility is that their cognitive decline led to a depressed mood. (21) If elderly persons perceive symptoms of cognitive decline and decreased control over their lives, depressive symptoms could develop or become exacerbated. (4,26) However, it is also possible that some of the observed mood symptoms are accompanying symptoms of the dementia itself. Diagnosing depressive disorders in persons with dementia will prove to be a diagnostic puzzle for physicians. Since demented residents who show mood symptoms are less likely to receive a diagnosis of depressive disorder than non-demented residents, demented residents are more at risk of under-diagnosis than non-demented residents. For this reason, nurse assistants and other caregivers should take more notice of the mood symptoms of demented residents. Further, a physician should decide whether a depressive disorder should be diagnosed and consequently monitored or treated.

COMPARISON WITH THE LITERATURE

Although three community-based studies reported a higher prevalence of depression in persons with dementia or cognitive decline than in non-demented or cognitively unimpaired elderly people, it was not clear whether this is also the case in residential care homes. (3,10,24) To our knowledge, two recent studies explored the prevalence of depressive disorders and depressive symptoms in demented and non-demented residents of residential care homes. The first was an Australian study including 290 residents of low-level aged care. (7) In this study, cognitive impairment was measured with the Standardized Mini Mental State Examination, in which scores between 25 and 30 indicated normal cognitive function, while scores between 19 and 24 indicated mild cognitive impairment, and scores between 10 and 18 indicated moderate cognitive impairment. A major depressive disorder was diagnosed with a structured clinical interview for DSM-IV axis I disorders. In the second study, among 201 residents of Dutch residential care homes, the presence of dementia was assessed with the Clinical Assessment Battery of the Consortium to Establish a Registry for Alzheimer’s Disease, which included the DSM-III-R criteria for dementia. (14) Depressive syndromes and symptoms were measured with a full psychiatric assessment using the Geriatric Mental State. The Australian study, reported that major depressive disorders were more present in residents with moderate cognitive impairment (27.5%) compared to residents with mild cognitive impairment (14.6%) or normal cognitive function (15.5%). (7) In contrast, only a small and non-significant difference was found between demented (15.2%) and non-demented residents (10.9%) in the prevalence of depressive disorders in the Dutch study. (14) In our study, the prevalence of diagnosed depressive disorders did not differ significantly between demented (26.8%) and non-demented residents (23.1%). Concerning depressive symptoms, there is only one study with which to compare our results. Janzing et al. found no difference in the prevalence of depressive symptoms between demented and non-demented residents, whereas in the present study mood symptoms were more prevalent in demented residents. (14) The differences in prevalence found in the previous studies can at least partly be explained by the methods used. In the present study, all depression diagnoses that were relevant for the personal care plan were taken into account. This included present disorders, but also disorders in remission for which monitoring was...
recommended. Therefore, the prevalence of diagnosed depressive disorders in our study may have been higher compared to other studies that used clinical research assessment instruments to diagnose current depressive disorders. In addition, the instruments used for diagnosing dementia or cognitive impairment were different between studies, which is another possible explanation for the differences between the results. Moreover, there was high diversity in the response rate: Janzing et al. included only 33% of the source population, and in the present study 99% of the cases was explored. The lower response rates could have introduced a bias in the comparison between demented and non-demented residents.

STRENGTHS AND LIMITATIONS Routine care outcome measurements including validated instruments were used for data collection in residential care homes, resulting in a nearly complete dataset. Since no informed consent was required, non-response of the residents did not bias the findings. To investigate the prevalence of diagnoses made in the usual care process no special screening for disorders was carried out. This study also has some limitations. Firstly, although Dutch clinical guidelines recommend DSM-IV criteria to diagnose depression and dementia, we remain uncertain to what extent general physicians and medical specialists applied these diagnostic criteria in diagnosing dementia and depressive disorders. Furthermore, the recognition of these disorders by the medical practitioners was likely not 100%. Since the usual care process was the subject of the study, this did not impede the statistical analysis. Secondly, if a resident had recovered after a period of disease, a physician had to confirm the return to health and remove the diagnosis from the personal care plan. Diagnoses could have been unjustly registered, since the recovery had not yet been confirmed by a physician. Thirdly, the nurse assistants who completed the inter RAI-LTCF were trained to register observed behaviour objectively and were assisted by an expert-supervisor. Although unlikely, (systematic) errors in rating depressive symptoms in residents with and without dementia could not completely be ruled out. Furthermore, the reliability and validity of the updated edition of the inter RAI-LTCF have been investigated, but are not yet published. The Depression Rating Scale based on the old RAI-LTCF, was not suitable because of substantial changes to the ratings (previously score 0-2 over 30 days on items, now 0-3 over 3 days on 11 items). Since the internal consistency of the 11 mood items was high, we felt confident in using their sum score to explore differences between demented and non-demented residents. Finally, it should be noted that the prevalence of diagnosed depressive disorders is different from the real prevalence of depressive disorders, since the prevalence of diagnoses contains information about the prevalence and recognition of disorders that may have been in remission for some time.

CONCLUSION

Since demented residents suffered more from mood symptoms and were less likely to be diagnosed with a depressive disorder than non-demented residents, demented persons may be at risk of under-diagnosis of depression.

ABSTRACT

OBJECTIVE To estimate and compare the prevalence and incidence of delirium and its risk factors in residents of Dutch nursing homes and residential care homes.

METHODS Data were extracted from the Long Term Care Facility (inter RAI-LTCF) version of the Resident Assessment Instrument which was filled in a routine care cohort for a total of 3627 residents. 828 residents of 6 nursing homes and 1365 residents of 23 residential homes were included in the analyses. Delirium was defined as a positive score on the adjusted Nursing Home–CAM.

RESULTS The prevalence of delirium was 8.9% in the nursing homes and 8.2% in the residential homes. The incidence was highest in the nursing homes with 20.7 versus 14.6 per 100 person years. Multivariate tests of risk factors for developing delirium included chair restraints (OR 2.3; 95% CI 1.27–4.28), dementia (OR 3.3; 95% CI 2.03–5.24) and Parkinson’s disease (OR 2.3; 95% CI 0.96–5.63) for residents in nursing homes, and dementia (OR 1.8; 95% CI 1.31–2.55) and fall incidents (OR 1.7; 95% CI 1.20–2.48) for residents in residential care homes.

CONCLUSIONS The prevalence and incidence of delirium was high in both nursing homes and residential care homes. More focus on modifiable risk factors such as the use of restraints in nursing homes and fall incidents in residential care homes may help to prevent delirium.
INTRODUCTION

Delirium is a cognitive disorder characterized by acute onset, fluctuating course, and among others disturbances of consciousness, attention and perception. Especially its fluctuating course frustrates diagnosis by staff not skilled in structural observation. The prevalence and incidence of delirium in older people institutionalized in residential care homes and nursing homes is not well known. Previous studies mostly report on delirium in hospitalized older people, where prevalence estimates vary between 15% and 24%. (3,4,5) Reported rates of incidence of delirium among older people admitted to hospitals range from 5% to 35%. (6,5,7) Dosa et al. reported between 16 and 23% of possible cases of delirium in a subgroup of post-acute hospitalized older patients discharged to nursing homes depending on the diagnostic criteria used. (8) Recently Mc Cusker et al. reported a prevalence of 3.4% and a 6 month incidence of 1.6 per 100 person weeks in residents of long term care facilities without cognitive impairment. These figures were respectively 33.2% and 6.9% in residents with cognitive impairment. Failure to treat delirium may lead to adverse conditions, such as a decrease in cognitive functioning, increase of falls and even death. (6) Recent research suggests that delirium is associated with an increased risk of developing dementia. (9) In view of these adverse health consequences, early recognition of delirium is important in order to treat the underlying disease and improve outcomes. Preventative efforts could become more targeted with more precise information about the risk indicators. Medical care in Dutch nursing homes is delivered by specialized physicians in long term care of patients with complicated chronic diseases. Nursing homes offer geriatric rehabilitation as well as long term and palliative care. Nursing homes provide professional care by highly trained staff including licensed practical nurses and psychotherapists. The residents of the residential care homes are vulnerable elderly persons, who need assistance with activities of daily living (ADL), supervision or sheltered accommodation. The family physician is responsible for the medical care of these residents. Staff in residential care homes is less trained and includes certified nursing assistant and rarely licensed practical nurses. The aim of this study was to compare the prevalence and incidence of delirium between Dutch nursing homes and residential care homes, as well as to identify the associated risk factors.

METHODS

DESIGN AND SETTING In this naturalistic cohort study we used data of the RAI database of the VU University Medical Centre. This database contains longitudinal assessments with the interRAI Long Term Care Facility instrument of residents used in usual care on all residents of six Dutch nursing homes and 23 Dutch residential homes. RAI assessments took place every 3 months and when there was an important change in health. Informed consent was not required as the data concerned anonymous routine care data. The nursing homes are comparable with nursing homes and the residential care homes with residential care facilities in the US. Both facilities are publicly funded and subject to governmental inspection and approval. The facilities are situated in rural as well as urbanized regions. All citizens have equal access to both facilities.

SUBJECTS AND PROCEDURE Residents were excluded if the observations missed information about delirium. The sample without information was in both settings more ADL dependent and represented in the nursing homes more widow(er). To calculate the incidence of delirium we excluded all prevalent cases (and residents without any follow up assessment). Figure 1 shows a flowchart of the included and excluded residents.

DATA COLLECTION Data collection took place from June 2005 to January 2010 using a web-based application of the inter RAI-LTCF, an updated version of the Minimum Data Set of the Resident Assessment Instrument 2.0 for Long Term Care Facilities (RAI-LTCF) (Inter RAI, 2008). (10) Inter RAI-LTCF provides an overview of the medical, physical, psychological, behavioural and social status of the residents. This has been employed since 2005 to monitor the health of residents and thereby improve the quality of health care. In both the nursing homes and the residential care homes, specially trained and supervised nursing assistants or licensed practical nurses completed the assessment every 3 months. The training consisted of two day courses, where they learned to work with the inter RAI-LTCF and studied the manual. While using the inter RAI-LTCF in daily practice they could frequently ask questions to an expert-supervisor. The assessors received an annual update training session of half a day.

OUTCOME MEASURES

DELIRIUM DEFINITION The presence of delirium was defined as a positive score on the Nursing Home–Confusion Assessment Method (NH-CAM). (8) The NH-CAM was based on a rearrangement of the inter RAI-LTCF variables to mimic the well-validated Confusion Assessment Method (CAM). It has recently been developed by Dosa et al. and was found to have good face and content validity. (8) In order to translate the items of the inter RAI-LTCF into the NH-CAM we used the inter RAI-LTCF Cognitive Performance Scale (CPS), scores from 0 (cognition intact) to 6 (very severe cognitive impairment) (Crohnbach’s α = 0.88) (11), the inter RAI-LTCF Depression Rating Scale (DRS). (12) The DRS has scores ranging from 0 to 14; scores 0-2 means no indication of depressive symptoms, 3 or higher...
indicates possible depression (Crohnbach’s α .73). (13) Increases in behavioural problems were measured with 6 behavioural items; wandering, verbal aggression, physical aggression, social disturbing behaviour, sexual unadapted behaviour and resists given care; scores from 0-4 (0= not present, 1= present but not in the last three days, 2= present on 1 or 2 of the last 3 days, 4= daily present). A minimal reliable change in the DRS and CPS, and behavioural problems were defined as an increase on these scales of more than one standard error of the mean between the first and second time assessment (DRS:0.030 , CPS: 0.021, increase of behavioural problems:0.033), as well as either one or more of the four items of possible delirium symptoms (c5a: easily distracted, c3b: episodes of disorganized speech, c3c: mental function varies over the course of the day and c4: acute onset and fluctuating course). Box 1 shows an overview of the translation.

Box 1: overview of translated items of inter RAI –LTCF in order to mimic the NH-CAM

1. Defining the Nursing Home Confusion Assessment Method (NH-CAM). CAM and NH-CAM identify subjects as having full delirium if features 1 and 2 are present with feature 3 or 4 and NH-CAM defined subjects as having no delirium if none of the four features are present. DRS scale: Depression Rating Scale

PREVALENCE OF DELIRIUM
Prevalence of delirium was defined as the presence of delirium (according to the NH-CAM) at the second assessment. The prevalence of delirium was determined using changes between the first two assessments. (Box 1)

INCIDENCE OF DELIRIUM
A person was deemed to be an incident case when two criteria were met: 1) absence of delirium at baseline, 2) presence of delirium at at least one follow-up assessment. Criterion 1 was used to ensure that the analysis was restricted to the group at risk for delirium; criterion 2 to ascertain delirium status at one of the follow-up measurements. The incidence rates of delirium for nursing homes and residential care homes were calculated per 100 person-years by dividing the number of incident cases of delirium by the total observation time that the population at risk was free from delirium. Because drop-out could occur during follow-up, we calculated annual incidence rates per 100 person-years.

The selection of potential risk factors was based on the risk factors known from previous studies. (6,14,15,16,17)

Demographic variables included: age dichotomized at the median (85 or older versus 0-84), gender (male /female).

Chronic diseases included: (a) depression, (b) Parkinson’s disease, (c) diabetes, (d) dementia, (e) cardiovascular diseases (including cerebral vascular accidents, coronary disease, chronic heart failure, vascular diseases, cardiac arrhythmia and hypertension). These diseases were considered present when documented in the residents’ medical record. They were based on family physicians’ or specialists’ diagnoses.

Care related variables included: use of bedrails, trunk restraints, and chair restraints, all coded as: daily presence yes/no.

Psychological variables included: anxiety observed in the last three days (present on at least 1 of the last three days/not present in the last 3 days), use of antipsychotics as noted on the medical list of the inter RAI-LTCF (yes/no).

Functional variables included: (a) urinary incontinence (daily presence yes/no), (b) fall incidents (at least one fall incident in the last 90 days yes/no), (c) fractures in last 30 days (yes/no), (d) ADL-dependency dichotomized at the mean: 0-17 versus 18-54, sum score of 9 items on help needed for activities of daily living (Crohnbach’s alpha 0.95) in which a higher sum score reflects a higher dependency, (e) hearing impairment (having some difficulty and using a hearing aid yes/no), (f) visual impairment (having some difficulty and using glasses yes/no), (g) recent infections including pneumonia and urinary tract infections (observed in the last 30 days yes/no), (h) pain symptoms 0-2 versus 3-11 dichotomized at the median sum score of 4 items on frequency, intensity, duration and occurrences of pain observed in the last 3 days. The higher the sum score the more pain was observed. Internal consistency expressed in Crohnbach’s alpha was 0.86. (i) Bedridden in the last 3 days (yes/no).

STATISTICAL METHODS
Prevalence of delirium was calculated by dividing the number of cases with delirium at baseline by the total number of eligible residents. Persons with prevalent delirium were excluded to calculate the incidence and analyze the risk factors of incident delirium. To determine the incidence of delirium we calculated the Incidence Rates for nursing and residential care home residents per 100 person-years. Logistic regression analyses were carried out to determine the combination of risk factors that best predicted the incidence of delirium. First, univariate analyses were used to select variables associated with incident delirium (p < 0.20). Second, these factors were entered in a multivariate regression model. Risk factors were removed manually with the stepwise backward selection procedure, until all variables showed a significant association with the outcome (p < 0.05). Time-to-first event was measured from the date of the second observation (baseline). Persons who were delirium-free during the entire follow-up period and persons who dropped out of the cohort were censored on the date of the event or at the date of their last assessment. Survival curves of the populations were compared by Cox regression analysis, adjusted for the variables, which were significantly related to the hazard (de¬mentia, Parkinson’s and fall incidents). Differences in the incidence of delirium between residential care and nursing homes were expressed with the hazard ratio. All analyses were carried out with SPSS version 15.0.
RESULTS

STUDY SAMPLE A total of 828 residents of six nursing homes and 1365 residents of 23 residential care homes were included in the study on the prevalence of delirium. In order to analyze the incidence and risk factors for the onset of delirium, we selected the persons without delirium up to the first follow-up in nursing homes (n = 640) and residential homes (n = 1027). Characteristics of residents with and without prevalent delirium are presented in Table 1 for both homes separately. In the nursing homes a higher percentage of the residents with prevalent delirium were more ADL dependent, had dementia and daily urinary incontinence. In the residential care homes a higher percentage had dementia and was more ADL dependent. The total observation time of the study population in the nursing homes was 10.8 months and 15.5 months in the residential care homes.

PREVALENCE AND INCIDENCE OF DELIRIUM The prevalence of delirium was 8.9% (74/828) in the nursing homes and 8.2% (112/1365) in the residential care homes. In the nursing homes 106 residents were newly diagnosed with delirium and in residential care homes 179 residents developed delirium. This corresponds with an IR of 20.7 per 100 person-years and 14.6 per 100 person-years in the residential care homes. Residents in nursing homes had a 1.5 higher risk of developing delirium compared to residential care home residents. This may be related to the fact that persons in the nursing homes were more ADL dependent, had a higher rate of daily incontinence and were restrained more often (bed rails, trunk restraints and chair restraints). Multivariate analysis showed that the risk of developing delirium in the nursing homes was highest in patients with dementia, Parkinson’s disease and those who were restrained in a chair. In the residential care homes, the risk of developing delirium was highest for residents with dementia and residents who had experienced at least one fall incident in the last 3 months. Both chair restraints and fall incidents have been reported previously as risk factors. These factors can be considered indicators of quality of care and are modifiable. The strengths of this study were the following: firstly, it represented a large sample collected from 6 different nursing homes and 23 different residential care homes. Secondly, this routine care cohort provided a strong external validity as residents were not excluded systematically and data collection did not depend on informed consent. This study also has some limitations. Firstly, using an updated version of RA1-LFCD our adjustment of the NH-CAM was partly identical to the NH-CAM Dosa et al. developed. Therefore, a direct comparison of the prevalence and incidence of delirium across studies should be done with caution. Secondly, neither the original NH-CAM nor our adjusted version was validated yet against a clinical diagnosis of delirium. The attention given with the assessment observations to changes in behaviour and cognitive function in demented residents may result in early detection of possible symptoms of delirium. Thirdly, given the fact that the population studied is very vulnerable, it is possible that the persons most at risk for developing delirium were lost in an

RISK FACTORS FOR THE ONSET OF DELIRIUM The univariate and multivariate relationships between the potential risk factors and the onset of delirium for both homes are presented in Table 2. From the multivariate model, we found chair restraints and dementia to be significant risk factors for incident delirium. In the residential care homes fall incidents and dementia were significant risk factors to developing delirium.

DISCUSSION

In this study we found a prevalence of delirium in both nursing homes and residential care homes of 8.9% and 8.2% respectively. The incidence was 20.7 per 100 person years in the nursing homes and 14.6 per 100 person years in the residential care homes. Residents in nursing homes had a 1.5 higher risk of developing delirium compared to residential care home residents. This may be related to the fact that persons in the nursing homes were more ADL dependent, had a higher rate of daily incontinence and were restrained more often (bed rails, trunk restraints and chair restraints). Multivariate analysis showed that the risk of developing delirium in the nursing homes was highest in patients with dementia, Parkinson’s disease and those who were restrained in a chair. In the residential care homes, the risk of developing delirium was highest for residents with dementia and residents who had experienced at least one fall incident in the last 3 months. Both chair restraints and fall incidents have been reported previously as risk factors. These factors can be considered indicators of quality of care and are modifiable. The strengths of this study were the following: firstly, it represented a large sample collected from 6 different nursing homes and 23 different residential care homes. Secondly, this routine care cohort provided a strong external validity as residents were not excluded systematically and data collection did not depend on informed consent. This study also has some limitations. Firstly, using an updated version of RA1-LFCD our adjustment of the NH-CAM was partly identical to the NH-CAM Dosa et al. developed. Therefore, a direct comparison of the prevalence and incidence of delirium across studies should be done with caution. Secondly, neither the original NH-CAM nor our adjusted version was validated yet against a clinical diagnosis of delirium. The attention given with the assessment observations to changes in behaviour and cognitive function in demented residents may result in early detection of possible symptoms of delirium. Thirdly, given the fact that the population studied is very vulnerable, it is possible that the persons most at risk for developing delirium were lost in an
early stage of the study. They were probably more often admitted in hospitals or scheduled for nursing home admission this may have caused an underestimation of the incidence.

Fourth, the nursing assistants who completed the inter RAI-LTCF were trained to register observed behaviour objectively and were assisted by an expert-supervisor. Although unlikely, (systematic) errors in rating symptoms of delirium in residents could not completely be ruled out. Finally, the use of the inter RAI-LTCF may result in delirium being detected and treated earlier in comparison to homes that do not have routine outcome monitoring.

The risk factors we found are probably related to the characteristics of our population (the “oldest” old and most frail elderly), but also to the specific conditions of long-term care facilities where quality of care is under pressure nationally and internationally.

**CONCLUSION**

This study shows that delirium is a common condition in both nursing homes and residential care homes. In view of the identified risk factors, special attention should be paid to the use of restraints and fall incidents in residential homes in order to decrease the risk of delirium developing in these populations. Full attention should be paid to the training of staff responsible for the care of residents in both nursing homes and residential care homes in observing symptoms of delirium. The inter RAI-LTCF may be a good tool for the early identification and treatment of the risk factors of delirium, but other well-validated observation instruments are also available. (18,6,15,16,19) Policy in nursing homes should advocate that restraints are only used in strictly prescribed situations (20) and that management in residential care homes should pay more attention to the residents’ environment in order to reduce fall incidents.

CHAPTER 9

SUMMARY AND GENERAL DISCUSSION

M. Boorsma-Meerman

The main focus of this thesis was the effects of a multidisciplinary integrated care approach on quality of care. Moreover we studied the incidences of mental dysfunctions for residents in Dutch residential care homes and nursing homes. The initiative for this research project underlying this thesis was financially supported by the Netherlands organisation for health research and development (ZonMw). The research project started in 2007 and ended in June 2010. At the start of the project we realised that there are three main problem areas in current Dutch institutionalised aged care. Health care is insufficiently patient-orientated and integrated. The role of the elderly person and his/her environment is very limited. A greater degree of self-determination in the care process is possible, as well as a better alignment between the care and the care needs of the elderly person. In addition there is insufficient alignment between care providers. Health care providers are insufficiently timely in identifying frail elderly persons with unfulfilled care needs and health risks. Last but not least, knowledge and proven effective innovations are insufficiently implemented. The hypothesis was that implementing an integrated care approach on the basis of already existing principles of the chronic care model, would substantially improve the health care quality and by that the quality of life and well-being of the elderly living in de homes for the elderly. In this last chapter of the thesis we discuss the main findings, and some theoretical and methodological considerations. We will finalise the thesis with recommendations for further improving the quality of care for residents in residential care homes and future research on this complex group of patients.
MAIN FINDINGS

In chapter 3, the study on the effects of a multidisciplinary integrated care approach on the quality of care for and quality of life of residents in residential care homes compared to usual care is presented. This was studied in a pragmatic cluster randomised controlled trial involving ten Dutch residential care homes that included 462 residents with physical or cognitive disabilities. Five of the residential care homes applied multidisciplinary integrated care, and five provided usual care. The intervention consisted of three-monthly geriatric assessments of functional health including decision support with the inter RAI-Long Term Care Facilities instrument by trained nurse-assistants, discussion of the outcomes and care priorities with the family physician, the resident self and her/his family and finally monthly multidisciplinary meetings to discuss complex residents. The intervention homes performed significantly better on the sum score and on 11 out of 32 ‘quality of care’ indicators. Moreover, less mortality and a tendency for more positive opinions on the quality of care by intervention residents was observed. Functional ability, number of hospital admissions and health-related quality of life remained comparable between the two groups. In the intention-to-treat analyses, no differences in disability or quality of care as seen through residents’ eyes were found between the two groups of facilities. In the per-protocol analysis, residents in the intervention facilities tended to be more positive. Process of care outcomes indicate that training and empowerment of nurse-assistants, which was completed for all intervention homes, together with monitoring using the geriatric assessment instrument, were likely to be the most important ingredients for improvement of the quality of care. To conclude, compared with usual care, the multidisciplinary integrated care approach resulted in a higher quality of care for elderly people in residential care homes.

In chapter 4, we present the study of cost-effectiveness of the multidisciplinary integrated care approach. The economic evaluation was conducted from a societal perspective. Outcome measures included a weighted sum score of Quality of care indicators, functional health (COOP WONCA) and Quality Adjusted Life-Years (QALY). Missing cost and effect data were imputed using multiple imputations. Bootstrapping was used to analyze differences in costs and cost-effectiveness. The difference in costs between the usual care and multidisciplinary integrated care was not significant. The costs of providing multidisciplinary integrated care were at most €225 per resident, including implementation costs. Total costs were €2,061 in the intervention group and €1,656 for the usual care group (mean difference €405). The probability that the intervention was cost-effective was 0.95 or more for ceiling ratios larger than €129 regarding patient related quality of care. A multidisciplinary integrated care approach may be considered cost-effective in comparison with usual care.

In chapter 5, a study of the impeding and facilitating factors of the implementation of a geriatric assessment instrument (inter RAI-LTCF) as a driving element of multidisciplinary integrated care is described. These factors were studied in the initial phase and 3 years after using a mix of quantitative and qualitative methods. These methods comprised surveys, semi structured interviews and in-depth interviews. Facilitating factors at introduction were positive opinions of nurse-assistants and family physicians about the changes of the process of care and the anticipated improvement of quality of care. Nurse-assistants were positive about the applicability of the software to support the inter RAI-LTCF assessments. Impeding factors were time constraints to complete inter RAI-LTCF assessments and insufficient computer equipment. In the maintenance phase, the positive attitude of the manager and the perceived benefits of the care model were most important. Impeding factors after 3 years remained the lack of time to complete the assessments and lack of sufficient computer equipment. We concluded that impeding and facilitating factors were comparable in the initial and maintenance phase. Adoption of the inter RAI-LTCF assessment method depended on positive opinions of staff and management, continuing support of staff, predominantly in time, training and coaching, and the availability of sufficient computer equipment.

In chapter 6, a study on the incidence of depression and its associated risk factors in Dutch nursing homes compared with the incidence and associated risk factors in residential care homes, is described. Data were extracted from the Long Term Care Facility (inter RAI-LTCF) version of the Resident Assessment Instrument which was filled in a routine care cohort for a total of 3627 residents. 621 residents of 6 nursing homes and 988 residents of 23 residential care homes were included in the analyses. The incidence rate was 13.6 per 100 person-years and 10.2 per 100 person-years for residents of nursing homes and residential care homes respectively and higher than previous reported incidences. The independent risk factors for incidence depression in residents of nursing homes included dementia and a score of three or higher on the Depression Rating Scale. The risk factors in residents of the residential care homes included being male, having a cancer diagnosis and a score of two or higher on the Cognitive Performance Scale. Age over 85 showed to be protective in both settings. Hearing impairment showed to have a protective effect in the residential care homes and use of hearing aid in the nursing homes.

In chapter 7, a study on possible under diagnoses of depression in demented residents in residential care homes is described. In this cross-sectional study the prevalence of diagnosed depressive disorders and observed mood symptoms between demented and non-demented residents of Dutch residential care homes were compared. Routine outcome measurements by trained nurse assistants using the Resident Assessment Instrument of residents in sixteen residential care homes, were analysed in this study. No statistically significant difference was found between demented and non-demented residents in the presence of diagnosed depressive disorders. However, the observed mood symptoms were more prevalent in persons with dementia than in people without dementia. Among persons with mood-symptoms, demented residents were less likely to be diagnosed with a depressive disorder than non-demented residents. We concluded that the prevalence of diagnosed depressive disorders was comparable between demented and non-demented residents. However, demented residents suffered more from mood symptoms and may be at risk of under-diagnosis of depression.

In chapter 8, the prevalence and incidence of delirium in residents of residential care homes and nursing homes was reported as well as the risk factors associated with the onset of delirium. Data were extracted from the Long Term Care Facility (inter RAI-LTCF) version of the Resident Assessment Instrument which was filled in a routine care cohort for a total of 3627 residents. 828 residents of 6 nursing homes and 1365 residents of 23 residential care homes were included in the analyses. Delirium was defined as a positive score on the adjusted Nursing Home–CAM. The prevalence of delirium was 8.9% in the nursing homes and 8.2% in the residential care homes. The incidence was highest in the nursing homes with 20.7 versus 14.6 per 100 person years. The higher percentage of delirium in nursing homes may be related to the fact that persons in the nursing homes were more ADL dependent, had a higher rate of daily incontinence and were restrained more often (bed rails, trunk restraints and chair restraints). Multivariate analysis showed that the risk of developing delirium in the nursing homes was highest in patients with dementia, Parkinson’s disease, and those who were restrained in a chair. In the residential
care homes, the risk of developing delirium was highest for residents with dementia and residents who had experienced at least one fall incident in the last 3 months. These factors can be considered indicators of quality of care and could be modifiable. The risk factors that we found are probably related to the characteristics of our population (the “oldest” old and most vulnerable elderly), but also to the specific conditions of long-term care facilities where the quality of care is under pressure nationally and internationally. We concluded that the prevalence and incidence of delirium was high in both nursing homes and residential care homes. More focus on modifiable risk factors such as the use of restraints in nursing homes and fall incidents in residential care homes may help to prevent delirium.

**THEORETICAL AND METHODOLOGICAL REFLECTION**

**THEORETICAL.** The elements of the chronic care model according to Wagner et al. comprise a clinical information system, decision support, delivery system, and self-management support that lead to productive interactions between prepared proactive practice teams of care providers and informed activated patients. Moreover, the individual interaction between elderly people living in residential care homes and the nurse-assistant who has a direct responsibility, contributed to the improved outcomes in our study. In order to get this result we adapted the principles of the chronic care model to suit institutionalised elderly people. All of these elements were applicable with the exception of self-management support. The latter was hampered by severe disablement and cognitive impairment of the majority of the residents. Therefore, we trained the nurse-assistants in systematically monitoring residents and better communication with the residents, medical staff and families. The introduction and implementation of the multidisciplinary integrated care approach we used was as expected complex and demanded a substantial effort of the care organization. The implementation of the three monthly assessments with inter RAI-LTCF as a driving element of the multidisciplinary integrated care approach demanded the greatest effort on the part of the organisation, and the good use of this instrument is vital for the performance of the model. The impeding factors are described in chapter 5. The most persistent impeding factors concerned the shortage of time and lack of sufficient equipment, such as enough and good working computers. Therefore quarterly assessments of the residents proved to be impossible to maintain. So after the study period the number of assessments was diminished to every six months. Despite these barriers the implementation in the ten participating residential care homes in this study was introduced as routine daily care.

**METHODOLOGICAL.** This study is one of the few studies that targets care in residential care homes. Its pragmatic study design resembles clinical practice to a high degree, which increases the relevance of the study results. An additional strong point of this study is the fact that this is the first cost-effectiveness analysis study investigating the Inter RAI-LTCF in this particular population. Our main study was limited by the fact that the participants were frail elderly people living in residential care homes and comprised a high percentage of cognitively impaired residents. As a result, a portion of the data was collected from interviews with proxies. The judgments of proxies may have differed from the residents’ judgments. Therefore, we adjusted for proxy interview and cognitive status in our analyses. The cluster randomization produced an imbalance between the intervention and control homes in the number of participating residents and in some of the functional characteristics of the residents at baseline. Although we adjusted for the imbalance in functional characteristics, imbalance in the number of participating residents may have led to underpowered results. Variation across the intervention facilities in the application of the complete protocol (3%–66%) was another limitation. This variation can be explained by financial and administrative issues during the study period. The financial obligations for residential care facilities resulting from a new national funding system for residential care of elderly people caused uncertainty about job continuation, high turnover of managers and new priorities at the homes in this study. We found that functional ability, number of hospital admissions and health-related quality of life remained comparable between the multidisciplinary integrated care group and usual care group. In the intention-to-treat analyses, no differences in disability or quality of care as seen through residents’ eyes were found between the two groups of facilities. In the per-protocol analysis, residents in the intervention facilities tended to be more positive about the quality of care. Health related quality of life was measured using a short-form 12-item version of the Rand Health Insurance Study questionnaire. It is known by previous studies that elderly people aged over 85 have higher scores except for social functioning than elderly people aged 75-84. The oldest old may have lower standards of living. Many friends and relatives are already deceased or suffer from chronic diseases. This may explain the fact that we did not find differences in health related quality of life between the intervention group and the control group. Elderly people living in residential care homes have a heterogeneous mix of chronic conditions that naturally erode health over time, which makes it difficult to know if an intervention of this sort would be able to override the downward trend of health states associated with chronic conditions in such a short time span. As the duration of the trial was short, sensitive instruments were vital. Perhaps the generic quality of life outcome variables were not sensitive enough to pick up differences within such limited time interval. Data used for studies on depression and delirium were extracted from the VU naturalistic cohort on routine care monitoring with the Minimum Data Set of the Resident Assessment Instrument. Regarding the international large samples of assessments with the inter RAI versions and its reliability the outcomes of inter RAI assessments will represent the clinical health status of the resident. All current medical diagnoses relevant for the personal care plan are recorded in the disease diagnosis part of the inter RAI-LTCF. An important strength of using these data is the significant external validity: no selection of subjects was made for the data collection as this was part of routine care independent of the resident’s cooperation. This enabled us to include residents who would be excluded in other studies because of physical illness, cognitive dysfunction, insufficient communication or refusal. Although the nursing assistants who completed the RAI-LTCF were trained to register observed behaviour objectively and were assisted by an expert-supervisor, (systematic) errors in rating symptoms in residents could not completely be ruled out. For the study on incidences and associated risk factors of delirium we used the Nursing Home–Confusion Assessment Method (NH-CAM) developed by Dosa et al. As we used data from an updated version of interRAI-LTCF, we had to translate our items into the items of the NH-CAM. Although the fact that the original NH-CAM was found to have good face and content validity neither the original NH-CAM nor our adjusted version was validated yet against a clinical diagnosis of delirium.

**PRACTICAL IMPLICATIONS AND RECOMMENDATIONS**

The results of this study are suitable for settings such as residential care homes and nursing homes and even for elderly living in a community. In all of the primary care settings it may be beneficial to have a model to monitor the chronically ill and elderly to prevent a functional decline and acute hospitalisations. It is also important to have an instrument that not only delivers output on the patient levels but also on the management level. It should facilitate managers to monitor and increase the quality of care in a sector of health
care that is under enormous societal pressure to improve performance. The inter RAI-LTCF is such an instrument. Future research should look at the reasons as to why the residents in the multidisciplinary integrated care group were satisfied with the multidisciplinary integrated care approach and why it did not translate over to the other clinical outcome variables. Longer term cost-effectiveness analysis will provide a more reliable outcome as the results in this study were relatively short term.

**FUTURE IMPLICATIONS**

Many is already written about the deficiencies in care for patients with chronic diseases and for elderly people. Despite reports and recommendations of national and international Health Councils less than expected is accomplished and quality of care is under pressure. (3;5;9;10) The multidisciplinary integrated care approach as a variation on the chronic care model, does not offer a quick and easy fix; it is a multidimensional solution to a complex problem. However it is a tangible guide to improve practice and not an abstract theory. (1) It demands a paradigm shift of professionals, from individual responsibility to team responsibility with a higher contribution of non-physician personnel and a more central role for nurses. It demands better collaboration with primary care physicians, elderly care physicians and other professionals specialized in chronic care. Financial barriers should be eliminated and care providers should initiate the elements of the chronic care model. This study showed that it can be done.[1] Our study presents a substantial improvement in quality of care already achieved in a 6 months period. The nurse-assistants, the family physicians, the elderly care physician and psychologist representing the pro-active care team in our study were enthusiastic and still embracing all elements of this approach in their daily routine. The residents of the ten residential care homes and their family or relatives were satisfied with the improvement of the quality of care. This care model is also applicable in primary care settings to improve the quality of care for community dwelling elderly people. In these times of incredible visualisation possibilities you cannot sell a new care model on paper! To visualise the care process in a multidisciplinary integrated care approach we have made a professional movie with the funds of the vocational training institutes for family physicians and elderly care physicians led by the audiovisual centre of the VU. This movie has been made in one of the studied residential care homes with the co-operation of the residents and their relatives, staff, family physicians, elderly care physicians and psychologists. Besides for the main movie, you can also find a very nice instructional part for the use of inter RAI-LTCF. This fine movie can be seen at www.nedrai.nl.

NEDERLANDSE SAMENVATTING

M. Boorsma Meerman
Samenvatting

NIEUW IN OUD: EVALUATIE VAN EEN GERIATRISCH ZORG MODEL. EN STUDIES IN NEDERLANDSE VERZORGINGSHUizen.

Kwaliteit van zorg in verzorgingshuizen staat wereldwijd onder druk. De zorg voor de bewoners is complexer geworden door veroudering van de bewoners en beperking van het aantal verpleeghuisbedden. Het verzorgend personeel van verzorgingshuizen is vaak onvoldoende opgeleid om de toenemende complexiteit van de zorg aan te kunnen. De meeste zorgorganisaties willen wel innoveren en hun kwaliteit verbeteren maar missen de expertise en financiële middelen . Huisartsen zijn verantwoordelijk voor de medische in de verzorgingshuizen maar voelen zich vaak onvoldoende uitgerust qua tijd en kennis om deze complexe zorg te leveren. Effectieve interventies voor chronisch zieken is in het algemeen afhankelijk van een multidisciplinaire benadering. Een dergelijke benadering omvat een gestructureerde geriatrische beoordeling, geprotocolleerde controle op medicatie, ondersteuning van de patiënt in het zelf beslissen nemen en een intensief volgen van de patiënt. Bewoners van verzorgingshuizen hebben vaak meerdere chronische ziekten en worden door de gevolgen van deze ziekten bedreigd in hun functionele autonomie. Wij ontwikkelden daarom een multidisciplinaire integraal zorgmodel volgens het principe van het Chronisch Zorgmodel van Wagner et al. Dit multidisciplinaire integrale zorgmodel is niet gericht op de chronische ziekte zelf maar op de handmatige chronische ziekten met zich meebrengen. Het omvat een drie maandelijkse beoordeling van de bewoners met behulp van de voor langdurige zorg ontwikkelde versie van het Resident Assessment Instrument (inter RAI-LTCF). Wij hebben de gebruiksvriendelijke internet applicatie genaamd RAIview gebruikt in ons onderzoek. Dit instrument bestaat uit een, alle domeinen van de geriatie omvattende, vragenlijst die gekoppeld is aan probleemsignaleringen die de verzorgende een direct overzicht geven over de actuele gezondheidstoestand, de zorgenbehoefte en de mogelijkheden van de bewoner. De probleemsignaleringen zijn weer gekoppeld aan protocolen die de verzorgende helpen meer inzicht te krijgen in de aard en mogelijke aanpak van de gesignaleerde problemen. Aan de hand van de gesignaleerde problemen kan de verzorgende samen met de bewoner en/of zijn familie een zorgplan opstellen naar de wensen van de oudere zelf. Dit zorgplan wordt besproken met de huisarts en de verzorgende zet de afgesproken acties in gang en volgen de effecten daarvan. Ouderen met complexe zorgbehoefte kunnen in een multidisciplinair overleg (MDO) met de verantwoordelijke verzorgende (zorgplan, de huisarts, specialist ouderengeneeskunde en psycholoog besproken worden. Indien nodig kan de huisarts de specialist ouderengeneeskunde in consult vragen in complexe situaties. Er zijn bij ons weten tot nu toe geen studies gedaan naar de effecten van een dergelijk zorgmodel op de functionele gezondheid en kwaliteit van zorg bij bewoners van verzorgingshuizen. De effecten van het multidisciplinaire integraal zorgmodel op de kwaliteit van zorg en de kosten van een dergelijk zorgmodel vormen het belangrijkste onderwerp van deze studie.

In hoofdstuk 2 worden de uitkomsten van de studie naar de effecten van het multidisciplinaire integraal zorgmodel op kwaliteit van zorg en kwaliteit van leven voor bewoners van verzorgingshuizen beschreven. Het betreft een cluster randomiseerde gecontroleerde studie met 462 deelnemers. De studie is uitgevoerd in tien verzorgingshuizen in de regio West-Friesland die allen behoren tot één zorgorganisatie. In vijf verzorgingshuizen werd het nieuwe zorgmodel geïntroduceerd en de vijf nader huizen dienden als controle huizen en leverden de gebruikelijke zorg. Ondanks het feit dat er slechts zes maanden meten kon worden heeft het multidisciplinaire integraal zorgmodel in de interventie huizen een indrukwekkende verbetering van de kwaliteit van zorg teweeg gebracht. De interventie huizen scoorden op 30 van de 32 getemeten kwaliteitsindicatoren voor zorg beter (waarvan 11 significant) dan de controle huizen. De bewoners in de interventiehuizen beoordeelden de kwaliteit van zorg positiever dan de bewoners in de controle huizen. Meer dan 50% van de verzorgende en de betrokken huisartsen vonden hun deskundigheid verbeterd met gebruik van het inter RAI-LTCF. Ruim 80% van de huisartsen en ruim 64% van de verzorgende vonden het multidisciplinaire overleg inhoudelijk verbeterd. Iets minder dan 53% van de verzorgende gaf aan beter op de hoogte te zijn van de gezondheidstoestand van hun bewoner en dat gold voor bijna 64% van de huisartsen. Bijna 60% van de verzorgende en ruim 81% van de huisartsen vonden de samenwerking verbeterd. Hieruit kan geconcludeerd worden dat de ondersteuning van de verzorgende door training en coaching in het gebruik van een geriatrisch beoordelingsinstrument ingebed in de andere onderdelen van het zorgmodel belangrijke veranderingen zijn in de kwaliteit van zorg. Het vierde hoofdstuk beschrijft de studie naar de kosten van het multidisciplinaire integrale zorgmodel. De economische evaluatie is uitgevoerd vanuit een sociale perspectief. De uitkomsten omvatten een gewogen som score van kwaliteit van zorg indicatoren, functionele gezondheid ( COOP WONCA) en kwaliteit van leven ( QALY). De kosten van de toepassing van het multidisciplinaire zorgmodel waren ongeveer 225 euro per bewoner. De totale kosten bedroegen in de interventie groep 2,061 euro en in de controle groep 1,656 euro ( gemiddeld verschil: 405 euro). Daar staat de indrukwekkende verbetering van kwaliteit van zorg tegenover. Of een multidisciplinaire integrale zorgbenadering beschouwd worden als kosten effectief ten opzichte van gebruikelijke zorg, hangt mede af van de bereidwilligheid van beleidsmakers in de zorg om te investeren in kwaliteit van zorg.

Vervolgens wordt in hoofdstuk 5 de implementatie van het geriatrische beoordelingsinstrument (inter RAI-LTCF) als onderdeel van het geïntroduceerde zorgmodel bestudeerd. Het onderzoek naar belemmerende en bevorderende factoren werd op twee momenten in de tijd uitgevoerd; namelijk in de introductiefase en in de continuering fase na drie jaar met behulp van een combinatie van kwalitatieve en kwantitatieve methodes. Deze methodes omvatten vragenlijsten, semistructurede interviews en diepte interviews. Bevorderende factoren in de introductiefase waren de positieve mening van de verzorgende en huisartsen over de veranderingen van het zorgproces en de kwaliteit van zorg. Ruim 80% van de verzorgende gaf aan tevreden te zijn over de mogelijkheden van het inter RAI-LTCF voor coördinatie van het zorgproces. Ook waren de verzorgende positief over de gebruiksvriendelijkheid van RAIview ( de internet applicatie van inter RAI-LTCF). Belemmerende factoren waren tijdgebrek van de verzorgende en onvoldoende beschikbaarheid van computers. In de continuering fase bleken de positieve houding van de manager en de ervaren voordelen van het zorgmodel de belangrijkste bevorderende factoren te zijn. Maar ook in deze fase waren het tijdgebrek van de verzorgende en onvoldoende beschikbaarheid van computers de belangrijkste belemmerende factoren. De conclusie uit dit onderzoek is dat de belemmerende factoren in de introductie fase en continuering fase vergelijkbaar zijn. De mate van acceptatie van de RAIview beoordelingsmethode is afhankelijk van de positieve mening van verzorgende en management, de continue ondersteuning van verzorgende en de beschikbaarheid van voldoende computer uitrusting.

Hoofdstuk 6 tot 8 bevat studies naar het voorkomen van depressie en delier en de onderdelen van het zorgmodel. De van de bewoner en de betrokken huisartsen vonden hun deskundigheid verbeterd. De toepassing van het multidisciplinaire zorgmodel waren ongeveer 225 euro per bewoner. De totale kosten bedroegen in de interventie groep 2,061 euro en in de controle groep 1,656 euro ( gemiddeld verschil: 405 euro). Daar staat de indrukwekkende verbetering van kwaliteit van zorg tegenover. Of een multidisciplinaire integrale zorgbenadering beschouwd worden als kosten effectief ten opzichte van gebruikelijke zorg, hangt mede af van de bereidwilligheid van beleidsmakers in de zorg om te investeren in kwaliteit van zorg.
uitgevoerd met behulp van data uit de RAI database van het VU medisch centrum. In hoofdstuk 6 wordt de incidentie van depressie en de risico factoren voor het krijgen van een depressie voor bewoners in 23 verzorgingshuizen en in zes verpleeghuizen onderzocht en vergeleken. Data van in totaal 3627 bewoners waarvan 621 in de verpleeghuizen en 988 in de verzorgingshuizen zijn voor deze studie gebruikt. Deze data zijn verkregen middels invulling van inter RAI-LTCF als onderdeel van gebruikelijke zorg in deze huizen. De incidentie bedroeg 13.6 per 100 personenjaren voor verpleeghuisbewoners en 10.5 per 100 personen-jaren voor verzorgingshuisbewoners. Deze incidenties zijn hoger dan die uit eerdere studies. De risico factoren voor het krijgen van een depressie waren in de verpleeghuizen dementie en een score van drie of hoger op de Depressie Schaal (Depression Rating Scale of DRS , één van de uitkomst schalen van het interRAI-LTCF). De risico factoren in de verzorgingshuizen omvatten het man zijn, enige vorm van kanker en een score van 2 of hoger op de Cognitief Presteren Schaal (Cognitive Performance Scale of CPS, uitkomst schaal van inter RAI-LTCF). Het ouder zijn dan 85 bleek een beschermend effect te geven in beide voorzieningen en gehoorverlies bleek dat te zijn in de verzorgingshuizen en het gebruik van een hoorapparaat in de verpleeghuizen.

Hoofdstuk 7 bevat een studie naar verschillen in depressie bij dementen en niet dementen en de vraag was of depressie bij dementen minder goed herkend wordt. Er werd geen significante verschil gevonden tussen demente en niet demente bewoners van verzorgingshuizen wat betreft het aantal gediagnosticeerde depressies. Echter bij dementen was de prevalentie van waargenomen stemming stoornissen hoger dan bij niet demente bewoners. In deze groep kregen dementen minder vaak de diagnose depressie met het risico onder behandeld te worden.

Hoofdstuk 8 gaat over de prevalentie en incidentie van dierel en de daarbij behorende risico factoren bij bewoners van 23 verzorgingshuizen en 6 verpleeghuizen. De gegevens van in totaal 3627 bewoners waarvan 828 in de verpleeghuizen en 1365 in de verzorgingshuizen zijn in deze studie gebruikt. Deze gegevens zijn beschikbaar in de VU data base en met routine matig gebruik van inter RAI-LTCF als onderdeel van de gebruikelijke zorg in deze huizen verzameld. In deze studie vonden we een prevalentie van delier van 8.9% in de verpleeghuizen en 8.2% in de verzorgingshuizen. De incidentie van 20.7 per 100 personen jaren in de verpleeghuizen en 14.6 per 100 persoonsjaren in de verzorgingshuizen bevestigden ons vermoeden dat de bewoners van deze types huizen een groot risico lopen op het ontwikkelen van een delier. De bewoners van verpleeghuizen hebben een 1.5 keer zo groot risico om een delier te krijgen als de bewoners van verzorgingshuizen. Dit zou kunnen samenhangen met het feit dat bewoners van verpleeghuizen meer ADL afhankelijk zijn, een hoger percentage van dagelijks incontinentie hebben en vaker gefixeerd waren (bedhekken, lichaamsfixatie en fixatie in de stol). Als risicofactoren voor het krijgen van een delier kwamen in de verpleeghuizen dementie, de ziekte van Parkinson en gefixeerd zijn in de stol naar voren. Voor de bewoners van de verzorgingshuizen waren de risicofactoren dementie en minstens één keer gevallen zijn in de laatste 3 maanden. Zowel fixatie in de stol als valincidenten zijn al eerder gerapporteerd als risico factoren. Deze factoren kunnen ook beschouwd worden als risico indicator voor kwaliteit van zorg en kunnen mogelijk verbeterd worden.

CONCLUDEREND

Kunnen we zeggen dat het invoeren van een multidisciplinaire integrale zorgmodel in verzorgingshuizen, zoals in onze studie, een indrukwekkende verbetering van kwaliteit van zorg kan geven. Binnen dat zorgmodel zijn het coördineren en monitoren van zorg door getrainde verzorgenden de belangrijkste ingrediënten. Het trainen en coachen bestond uit het leren uitvoeren van een halfjaarlijkse geriatrische beoordeling, het opstellen van een zorgplan waarin de wensen van de bewoner centraal staan en het leren bespreken daarvan met de huisarts. Het multidisciplinaire overleg bleek in dit zorgmodel door de structurering middels het zorgplan inhoudelijk kwalitatief verbeterd waardoor deze overleggen voor de huisarts rendeerden. Of een dergelijk zorgmodel als kosten effectief beschouwd kan worden hangt mede af van de bereidheid van beleidsmakers om in kwaliteit van zorg te investeren. Verder is gebleken dat depressie en delier niet alleen veel voorkomen bij bewoners van verzorgingshuizen en verpleeghuizen maar ook veelvuldig tijdens het verblijf in de instelling ontstaan. Beide aandoeningen tasten de kwaliteit van leven ernstig aan en hebben, als zij niet op tijd herkend en behandeld worden, een slechte prognose. De meest kwetsbare groep met risico op onderdiagnose blijkt de groep dementeerenden te zijn. Het gebruik van een beoordelingsinstrument zoals de internet applicatie van inter RAI-LTCF (RAIview) kan een belangrijk hulpmiddel zijn voor de verzorgende om depressie en delier op tijd te herkennen. Het onderzochte zorgmodel kan zonder al te veel aanpassingen in zowel verzorgingshuizen, verpleeghuizen als bij thuiswonende kwetsbare ouderen ingezet worden. Ook in de eerste lijn kan een zorg model dat geschikt is om chronisch zieken en kwetsbare ouderen te vervolgen teneinde functionele achteruitgang en acute ziekenhuisopnames te voorkomen gunstig uitpakken. Het is daarbij ook van belang om een instrument te hebben dat niet alleen uitkomsten op patiënt niveau levert maar ook op management niveau waardoor het management in staat is te sturen op kwaliteit. De Resident Assessment Instrumenten, waarvan de inter RAI-LTCF versie gebruikt is in deze studie, is tot nu toe het enige instrument dat zo compleet is. Daarbij levert dit instrument belangrijke onderzoeksdata, die in deze kwetsbare patiënten groep meezaam te verzamelen zijn.

TENSLOTTE

In deze snelle tijd verkoop een zorgmodel niet op papier! Om het zorgproces binnen het multidisciplinaire integrale zorgmodel te visualiseren hebben we met subsidie van het audiovisuele centrum van de VU een professionele film laten maken. Deze film is gemaakt in één van de verzorgingshuizen en met medewerking van bewoners, personeel, huisarts, specialist ouderengeneeskunde en psycholoog. Naast de hoofdfilm staat er ook een enthousiasmerende instructiefilm voor het gebruik van inter RAI-LTCF op de DVD. Deze prachtige film is te zien op www.nedrai.nl.
ABOUT THE AUTHOR

M. Boorsma Meerman
The author of this thesis was born on October 7th, 1949 in Vlaardingen, the Netherlands. She graduated from Secondary School in 1967 and started medical studies in September of that same year at the VU university in Amsterdam. After obtaining her medical degree in November 1974, she parted with her husband Pieter (a plant breeder graduated from Agriculture University Wageningen) for Morocco. She lived in Rabat and worked in Salé in a Rehabilitation Centre (Hôpital El Ayachi) for three years. After returning to Holland and already the proud mother of three little children she worked as a consultation physician for children from 0-4 years old in Enkhuizen. When the fifth and the last child reached the age of four years she started the two year course to become a family physician (1989-1991). She had a wonderful time in a partnership with Giel Nijpels as a family physician in Gezondheidscentrum Risdam in Zwaag. This lasted about ten years and ended because Giel Nijpels became a professor at the VU university in Amsterdam. She accepted a job in a nursing home in Hoorn and completed the two year course to become an elderly care physician (2002-2004). The study for this thesis started in 2005 while she was working as an elderly care physician in the Omring care organisation in Hoorn.

About the author

The author of this thesis was born on October 7th, 1949 in Vlaardingen, the Netherlands. She graduated from Secondary School in 1967 and started medical studies in September of that same year at the VU university in Amsterdam. After obtaining her medical degree in November 1974, she parted with her husband Pieter (a plant breeder graduated from Agriculture University Wageningen) for Morocco. She lived in Rabat and worked in Salé in a Rehabilitation Centre (Hôpital El Ayachi) for three years. After returning to Holland and already the proud mother of three little children she worked as a consultation physician for children from 0-4 years old in Enkhuizen. When the fifth and the last child reached the age of four years she started the two year course to become a family physician (1989-1991). She had a wonderful time in a partnership with Giel Nijpels as a family physician in Gezondheidscentrum Risdam in Zwaag. This lasted about ten years and ended because Giel Nijpels became a professor at the VU university in Amsterdam. She accepted a job in a nursing home in Hoorn and completed the two year course to become an elderly care physician (2002-2004). The study for this thesis started in 2005 while she was working as an elderly care physician in the Omring care organisation in Hoorn.
DANKWOORD

M. Boorsma-Meerman
Dankwoord

Dat dit proefschrift er nu ligt is aan heel veel mensen te danken. En wel zoveel dat ik waarschijnlijk mensen vergeet te noemen. Daarvoor bij voorbaat excuus. De volgorde waarin ik mensen noem is ook volstrekt willekeurig en houdt geen enkel verband met de mate van ondersteuning.

Ik begin daarom maar:

Allereerst wil ik alle bewoners en familie van de deelnemende verzorgingshuizen bedanken. Zij hebben aan lange interviews meegewerkt en waar ze het zelf niet meer konden hebben de familie dat gedaan.

Speciale dank voor meneer Klopper en zijn familie en mevrouw Groeneweg en haar familie voor het meewerken aan de film.

Alle evv’ers die er aan moesten geloven, bedankt. Ondanks tijdgebrek, bezuinigingen, wisselingen in management om maar een paar stormen te noemen bleven jullie overeind en hebben met verve het nieuwe zorgmodel vorm gegeven en doen dat nog. Petje af!

Ton Uivel en Marjo Ligthart, destijds Raad van Bestuur dank voor jullie betrokkenheid en steun voor dit project. Als jullie er niets in gezien hadden was het sowieso niet van de grond gekomen.

Alle betrokken managers van de deelnemende verzorgingshuizen bedankt voor jullie enthousiasme en volhardendheid in zulke vaak moeilijke omstandigheden. Let jou wil ik in het bijzonder noemen omdat je vanaf het eerste begin, de pilot, enthousiast was en dat tot nu toe gebleven bent. Een project als dit waarin kwaliteit van zorg centraal staat valt of staat met de ondersteuning van het management.

Ik wil Marlies en Don, evv’er en teamcoach van verzorgingshuis Almere in Opperdoes en Manja, psycholoog apart noemen omdat jullie ook nog aan de film mee wilde werken en daarmee een beetje beroemd zijn geworden.

Alle huisartsen in West Friesland die meegewerkt hebben aan dit onderzoek hartelijk dank. Jullie hebben het zorgmodel omarmd en zijn er vandaag aan de dag nog steeds enthousiast over. Ik wil Cees speciaal bedanken voor zijn rol in de film.

Alle interviewers en Evelyn bedankt. Zonder jullie inzet was een wetenschappelijke evaluatie niet mogelijk geweest.

Mini en Miraam wij vormden met zijn drieën de drie Musketiers en hebben het gevecht met volhardendheid en overredingskracht gewonnen. Het was een zeer boeiende ervaring.

Mini zonder jou als projectleider was het zeker niet gelukt. Je bent tot op de dag van vandaag nog diegene die dit zorgmodel schraagt en dagelijks vorm geeft. Het is dan ook te hopen dat de organisatie een waardige opvolger voor jou zal aanstelen als je van je pensioen gaat genieten. Ik heb veel van je geleerd! Bedankt daarvoor.

Miriam jij hebt als coördinator van TRAFO (een organisatie voor extramurale projecten in West Friesland, waarin het ziekenhuis, de huisartsen en de zorgorganisaties vertegenwoordigd zijn) voor een duurzaam draagvlak gezorgd binnen het bestuur van TRAFO, waardoor het project ondanks de vele bedreigingen toch door kon blijven gaan. Je bent een bijzonder mens voor mij.

Ik wil jullie ook bedanken dat jullie beide mijn paranimfen willen zijn.

Alle studenten die tijdens hun stage meegewerkt hebben aan het uitwerken van de gegevens dank ik hierbij hartelijk. Menke, Martine en Eveliene jullie hebben ook meegeschreven aan een artikel, geweldig, bedankt.

Giel jou dank ik voor het feit dat we niet los komen van elkaar en daar genoegen in scheppen.

Jij kan mijn eigengereidheid en ongrijpbaarheid verdragen.

Hein; het was een ‘hell of a job’ om iemand zoals ik tijdens een promotie traject te begeleiden. Ik vind dat je het fantastisch hebt gedaan en hoop dat we nog wat leuke projecten in de zorg kunnen realiseren voordat ik echt met pensioen ga.

Dinnus; bedankt voor je plezierige en rustige aanwezigheid. Ik heb veel geleerd van je grondige commentaren en heb veel waardering voor je standvastigheid.

Miel dankjewel voor je enthousiasme en meekijken.

Karlijn; zonder jou waren de laatste artikelen niet gepubliceerd. Gelukkig vergeleek je mijn gestuntel altijd met dat van je moeder en daarom kon je erom lachen.

Roel voor jou een extra dankjewel voor de prachtige film en dit prachtige boekje.

Zonder een fantastisch thuis en al meer dan 40 jaar dezelfde vent was ik hier nooit aan begonnen. Pieter; jij en ik hebben een onverwoestbare band en vijf zeer inspirerende kinderen met dito aanhang én een prachtig kleinkind. Ik ben de rijkste vrouw van de wereld.
interRAI Long-Term Care Facility (LTCF)

GI STATUS
1. Acid reflux—Regurgitation of acid from stomach to throat
2. Constipation—No bowel movement in 3 days or difficult passage of hard stool
3. Diarrhea
4. Vomiting

SLEEP PROBLEMS
1. Difficulty falling asleep or staying asleep
2. Napping during day
3. Tiredness

OTHER
1. Aspiration
2. Fever
3. GI or GU bleeding
4. Peripheral edema

DYSPEPSIA (Shortness of breath)
1. Absent at rest
2. Absent postural

FATIGUE
1. Inability to complete normal daily activities—e.g., ADLs, IADLs
2. None
3. Minimal—Diminished energy but completes normal daily activities
4. Moderate—Due to diminished energy, unable to finish normal daily activities
5. Severe—Due to diminished energy, unable to get out of bed

PAIN SYMPTOMS
1. Frequency
2. Intensity
3. Quality
4. Duration
5. Location

PAIN MANAGEMENT
1. Medication
2. Behavioral
3. Physical
4. Environmental

SECTION K. ORAL AND NUTRITIONAL STATUS
1. HEIGHT AND WEIGHT (INCHES AND POUNDS)
2. NUTRITIONAL ISSUES
3. RATIONALE FOR FEEDING TUBE
4. NUTRITIONAL INTAKE
5. PARENTERAL OR ENTERAL INTRACHEAL
6. DENTAL OR ORAL

SECTION L. SKIN CONDITION
1. MOST SEVERE PRESSURE ULCER
2. PRESENCE OF SKIN ULCER OTHER THAN PRESSURE ULCER
3. MAJOR SKIN PROBLEMS
4. SKIN TEARS OR CUTS
5. OTHER SKIN CONDITIONS OR CHANGES IN SKIN CONDITION
6. FOOT PROBLEMS

SECTION M. ACTIVITY PURSUIT
1. AVERAGE TIME INVOLVED IN ACTIVITIES
2. ACTIVITY PREFERENCES AND INVOLVEMENT ADAPTED TO CURRENT STATUS

SECTION O. TREATMENTS AND PROGRAMS RECEIVED OR SCHEDULED IN THE LAST 3 DAYS (OR SINCE LAST ASSESSMENT LESS THAN 3 DAYS)
1. TREATMENTS
2. PROGRAMS

ADDENDUM:

- Allergies to medications or devices
- Special dietary needs
- Other medications or treatments
- Additional information not included in the assessment

Note: Add additional lines as necessary for other medication or treatment plans.
### Section Q. Discharge Potential

1. **Discharge Potential**
   - No: [ ]
   - Yes: [ ]

   a. Expresses / indicates preference to return or remain in the community: [ ]
   b. Has a support person who is positive towards discharge or maintaining residence in community: [ ]
   c. Has housing available in community: [ ]

2. **How long person is expected to stay in the current setting or under the care of this service prior to discharge to community** (count from assessment reference date, including that day):
   - 0-7 days: [ ]
   - 8-14 days: [ ]
   - 15-30 days: [ ]
   - 31-60 days: [ ]
   - 61 or more days: [ ]
   - Discharge to community not expected: [ ]

### Section R. Discharge

1. **Last Day of Stay**
   - Year: 2
   - Month: 0
   - Day: [ ]

2. **Discharged To**
   - Private home / apartment / rented room: [ ]
   - Boarding home: [ ]
   - Assisted living: [ ]
   - Semi-independent living: [ ]
   - Mental health residence - e.g., psychiatric group home: [ ]
   - Group home for persons with physical disability: [ ]
   - Setting for persons with intellectual disability: [ ]
   - Psychiatric hospital or unit: [ ]
   - Homeless (with or without shelter): [ ]
   - Long-term care facility (nursing home): [ ]
   - Rehabilitation hospital / unit: [ ]
   - Hospice facility / Palliative care unit: [ ]
   - Acute care hospital: [ ]
   - Other: [ ]
   - Decreased: [ ]

### Section S. Assessment Information

**Signature of Person Coordinating / Completing the Assessment**

1. Signature (sign on above line):
2. Date assessment signed as complete:
   - Year: 2
   - Month: 0
   - Day: [ ]
