ABSTRACT The photosynthetic light-harvesting systems of purple bacteria and plants both utilize specific carotenoids as quenchers of the harmful (bacterio)chlorophyll triplet states via triplet-triplet energy transfer. Here, we explore how the binding of carotenoids to the different types of light-harvesting proteins found in plants and purple bacteria provides adaptation in this vital photoprotective function. We show that the creation of the carotenoid triplet states in the light-harvesting complexes may occur without detectable conformational changes, in contrast to that found for carotenoids in solution. However, in plant light-harvesting complexes, the triplet wavefunction is shared between the carotenoids and their adjacent chlorophylls. This is not observed for the antenna proteins of purple bacteria, where the triplet is virtually fully located on the carotenoid molecule. These results explain the faster triplet-triplet transfer times in plant light-harvesting complexes. We show that this molecular mechanism, which spreads the location of the triplet wavefunction through the pigments of plant light-harvesting complexes, results in the absence of any detectable chlorophyll triplet in these complexes upon excitation, and we propose that it emerged as a photoprotective adaptation during the evolution of oxygenic photosynthesis.

INTRODUCTION

During the first steps of the photosynthetic process, the absorption of photons by antenna proteins and the subsequent transfer of excitation energy to the reaction centers are both intimately linked with the potential production of dangerous oxidative species. To avoid photooxidative damage, photosynthetic organisms have developed a number of strategies to minimize the formation of reactive oxygen; these processes often involve carotenoid molecules (e.g., (1–7).). The best characterized of the photoprotective functions of carotenoid molecules in photosynthetic organisms involves quenching of (bacterio)chlorophyll ((B)Chl) triplets. Excited singlet states of (B)Chl molecules may decay to (B)Chl triplet states, with a low but significant yield. Since the energy of these triplet states is above that of the singlet state of oxygen, they may sensitize the formation of singlet oxygen, one of the most dangerous chemical species for living organisms (8). In photosynthetic proteins, the efficiency of this reaction is impaired by the competing transfer of the triplet state from (B)Chls to carotenoid molecules, which display a triplet-state energy below that of singlet oxygen. This quenching reaction reduces the lifetime of the (B)Chl triplet state by more than three orders of magnitude (9).

In light-harvesting (LH) proteins from purple bacteria, the triplet-triplet transfer from (B)Chl to carotenoid molecules has a characteristic lifetime in the nanosecond range (10,11). In most of these complexes, formation of the carotenoid triplet state has a significant, but limited, influence on the electronic transitions of (B)Chl molecules (10). The energy of the lowest electronic transition of the carotenoid triplet state is proportional to the inverse of the number of carotenoid C–C conjugated bonds, as predicted by theory (12,13). In contrast, carotenoid triplet states in the LH complexes (LHCs) of higher plants exhibit properties largely different from those found in LH proteins ((14) and Table 1). Formation of carotenoid triplet states in these complexes induces an intense bleaching of Chl transitions, and the triplet-triplet transfer lifetime, although not determined with precision, has been proposed to be ultrafast (15). In this article, we show that in the major LH protein from higher plants, LHCII, this transfer is fast enough that chlorophyll triplet is not accumulated in these complexes. Application of infrared absorption and resonance Raman spectroscopies provide a precise picture of the carotenoid triplet states in these complexes, which can be related to their electronic and functional properties.

MATERIALS AND METHODS

Protein and carotenoid purification

The LH2 protein from Rhodoblastus acidophilus 10050 was purified as described previously (16,17). LHC complexes were prepared from Spinacia oleracea photosystem-II-enriched particles by isoelectric focusing

*All values were obtained from previous studies as follows: for purple bacteria (10); for lutein prepared as trimers (14,42,43); for monomers (43,44), and for CP29* (43).* followed by sucrose gradient centrifugation (18). The carotenoid lutein was purified as described previously (19).

**Femtosecond transient absorption spectroscopy**

These measurements were carried out with a spectrometer described in a previous study (20). The output of the Ti:sapphire laser at 800 nm was frequency-doubled and used to excite the sample at 400 nm; the low-pass and 1850–1200 cm\(^{-1}\) MA). The IR light impinging on the sample was sent through 4000 cm\(^{-1}\) MCT detector (20 MHz, KV 100, Kolmar Technologies, Newburyport, MA). The experimental setup included an IR light source and a fast preamplified photovoltaic detector (SensIR) in ATR mode. Each three-dimensional IR interferogram is composed of 660 points in the spectral region 1800–1200 cm\(^{-1}\), giving a spectral resolution of 8 cm\(^{-1}\). The data presented are an average of three data sets; each set is an average of 20 time-resolved interferograms of which each point is a time slice that is the average of nine coadditions. The time-resolved interferograms have been further Fourier-transformed into time-resolved IR difference spectra (OPUS software, Bruker). The step-scan FTIR sample was made with a drop of 2 μL of OD 670 nm of ~500 spread between two tightly fixed CaF2 windows, without any spacer and greased for tightness. All experiments were performed at room temperature. The obtained time-resolved IR difference spectra were analyzed by global analysis (21) with a sequential kinetic model, which simultaneously fitted the dynamics at every point of a spectral data set. This analysis leads to decay-associated difference spectra (DADS), with associated lifetimes. The FTIR spectroscopy of lutein was performed on a Nicolet 6700 spectrometer (Thermo Scientific, Waltham, MA), equipped with an MCTA photoconductive detector (SensIR) in ATR mode.

**Raman spectroscopy**

Spectra, in resonance with the carotenoid transitions, were recorded with a Jobin Yvon U1000 spectrometer equipped with a UV-coated CCD camera (Spectraview 2D, Jobin Yvon, Longjumeau, France). For these experiments, spectra were recorded at 90° geometry from samples maintained at 77 K in a flow cryostat (Air Liquide, Sassenage, France) cooled with liquid nitrogen. An argon laser (Innova 100, Coherent, Santa Clara, CA) provided excitation wavelengths of 495.6, 501.7, 514.5, and 528.7 nm. To minimize systematic errors, no subtraction of the background signal was made. Laser power was controlled at the sample using a photocounting device (Vector H410, Scientech, Boulder, CO).

**RESULTS**

Fig. 1 shows the result of a global analysis of the time-resolved absorption spectroscopy data obtained upon nonselective excitation of trimeric LHCII at 400 nm. The first EADS (black line) shows the bleaching of the \( S_0 \rightarrow S_2 \) absorption transition arising from carotenoids below 515 nm, and of the transitions of Chl b and Chl a at ~650 nm and ~675 nm, respectively. It decays in 100 fs to the next spectrum (red trace), which is characterized by a pronounced carotenoid excited-state absorption at 537 nm, corresponding to the \( S_1 \rightarrow S_0 \) electronic transition of this molecule, a partial restoration of the \( S_0 \rightarrow S_2 \) carotenoid transition, and a strong bleaching of the chlorophyll transitions. The bleaching of the chlorophylls results from energy transfers, either intramolecular or from the carotenoid molecules. This red spectrum decays in 1 ps to the blue one, which is characterized by a more pronounced bleaching of the Chl a \( Q_y \) transitions, mainly due to excitation energy transfer from Chl b and carotenoids. The next evolution takes place in 14.9 ps and results in the green spectrum, which shows a decrease in bleaching of the Chl a \( Q_y \) transition, due to singlet-singlet annihilation processes, and the complete decay of the carotenoid \( S_1 \) state(s). The final evolution, which occurs in 3.9 ns, results in the magenta spectrum. This spectrum clearly shows that the decay of the Chl singlet excited state is complete in 3.9 ns, and that an absorption transition with properties typical of that of a carotenoid triplet state (displaying a maximum at 514 nm, together with a shoulder at
\(~525\) nm (13,14) appears concomitantly with the disappearance of the Chl excited state. The inset in Fig. 1 displays kinetic traces at 511 nm, i.e., close to the maximum of the T\(_1\) transition, and at 675 nm, which corresponds to the Q\(_y\) maximum of Chl molecules. A comparison of the two traces shows that the rise of the carotenoid triplet state occurs in parallel with the decay of the Chl singlet excited state. This unambiguously demonstrates that no chlorophyll triplet state is appreciably accumulated in these complexes after excitation, and thus that a fast and extremely efficient triplet-triplet channel exists, which very effectively quenches the chlorophyll triplet states as soon as they are formed. The results in this work are fully consistent with a recent EADS study on the peridinin-chlorophyll protein (PCP) from the dinoflagellate Amphidinium carterae, where the Chl to carotenoid transfer is similarly fast and where no significant transient formation of Chl triplet was observed (22).

To understand the mechanisms underlying this very efficient triplet-triplet transfer, we investigated LHCII by step-scan time-resolved FTIR spectroscopy. Upon excitation of LHCII carotenoids at 475 nm, the triplet decay was satisfactorily fitted with two components only, using global analysis. The first component decays with a time constant of 20 \(\mu\)s, whereas the second component, which does not account for more than 10% of the signal, does not decay within the time window of the measurement (~320 \(\mu\)s). Fig. 2A displays the first DADS normalized to the contribution of the keto group at 1653 cm\(^{-1}\). Taking into account the time-resolved absorption data displayed above, the first decay-associated spectrum must be assigned to the carotenoid triplet (Fig. 2A, black line, DADS1). In view of its long time, the second spectrum is attributed to unquenched Chl, i.e., a small proportion of triplet chlorophyll states that have not been transferred to the carotenoid molecules (Fig. 2A, blue line; DADS2). It has already been observed that a small fraction of chlorophyll triplet may not be quenched by the carotenoid molecules (23). Considering the results of time-resolved absorption, DADS1 should contain positive contributions of the carotenoid triplet state and negative contributions of its ground state. Although such contributions clearly appear in the difference spectrum (region termed luteins), additional bands are obviously present in this spectrum. Indeed, no intense contribution in the higher-frequency region is expected from carotenoid molecules (see Fig. 2B) (24). On the contrary, in this region, DADS1 is typical of the spectrum of a chlorophyll triplet in solvent, which is plotted in Fig. 2C for comparison (25,26). The negative contributions around 1700 cm\(^{-1}\) represent bleaching of bands arising from the stretching modes of conjugated keto carbonyl groups. These groups, when conjugated with the Chl macrocycle, experience large downshifts upon triplet formation, which results in positive contributions at lower frequencies. Nevertheless, DADS1 has a lifetime characteristic of carotenoid triplets, and so we conclude that in LHCII these chlorophyll infrared modes decay with the same lifetimes as carotenoid modes. Recently, an identical result was observed for the triplets in PCP (26,27).

In resonance Raman spectra of carotenoid molecules, in either their ground or triplet excited states, two groups of bands yield precise, important information on conformation and molecular structure: the so-called \(\nu_1\) and \(\nu_4\) regions. The \(\nu_1\) vibrational mode is usually the most intense band in carotenoid resonance Raman spectra. It arises from stretching modes of the conjugated C\(=\)C bonds of the molecule and its position, in the 1480–1550 cm\(^{-1}\) range reflects the bond order of the conjugated C\(=\)C bonds. The \(\nu_4\) band(s) arises from out-of-plane wagging modes of the carotenoid C-H groups, which, for symmetry reasons, are not coupled with the electronic transition in the case of a perfectly planar carotenoid molecule. Their resonance Raman activity, as well as their precise frequency, tightly
depend on any out-of-plane distortions these molecules experience.

Fig. 3 displays resonance Raman spectra (800–1650 cm$^{-1}$) of the LH2 complex from *Rbl. acidophilus* in resonance with the carotenoid rhodopin glucoside. (A) The subpopulation attributed to triplet carotenoid increases with laser power. (B) The deduced triplet-state Raman spectrum of rhodopin glucoside. $T = 77$ K, $\lambda_{ex} = 514.5$ nm.

In LHCI trimer from higher plants, both the bound luteins may accept triplet states from chlorophyll. The $T_{1} \rightarrow T_{n}$ triplet absorptions of these carotenoids peak (13,14) near the 514.5 and 528.0 nm excitation lines from an argon laser. The positions of these transitions are separated enough so that each of these triplets can be selectively observed in resonance Raman. This is in contrast to LHCI monomers and CP29, where the absorption spectra of the central luteins are degenerate, so that they both contribute equally to the measured spectra. Fig. 4 displays the $v_1$ and $v_4$ Raman bands of the lutein molecules in LHCI trimers, obtained when excited at 514.5 nm and 528.7 nm with low (black lines) and high (blue lines) laser intensities. It has been previously shown that the lutein 2 in higher plant LHCs is distorted, as seen by its Raman spectrum in the $v_4$ region (34). As for the LH2-bound carotenoid (Fig. 3 B), power-induced spectra obtained by difference highlight the characteristic downshifted triplet signal of the $v_1$ mode (Fig. 4 A, red traces).

As discussed in detail in Ruban et al. (35), the lowest electronic transitions of lutein 1 and 2 are located at 494 and 510 nm, respectively, and the triplet-triplet transitions of these molecules should accordingly contribute at 514 and 528 nm, respectively. The spectra of the ground- and triplet-states of lutein 1 are thus optimally obtained with excitation at 496 and 514 nm, respectively, whereas the contributions of the ground- and triplet states of lutein 2 require excitation at 510 and 528 nm. Thus, with an excitation wavelength of 514.5 nm at low power, the Raman spectra mainly arise from lutein 2 in its ground state, whereas the additional triplet bands observed at higher power arise from the lutein 1 molecule (cf. Table 1).
When exciting at 528.7 nm, the triplet contribution observed at high power must arise only from lutein 2. The resonance Raman spectra of carotenoids bound to monomeric LHClI, the minor antenna CP29 (not shown; see Table 2) and the inner PSII antenna CP43 (Fig. 4A) were also extracted using the same method. It is worth noting that for carotenoids in all antenna complexes, the frequencies and the shape of the bands in the $\nu_4$ region of resonance Raman spectra remain similar in both the ground and triplet states, in sharp contrast to the case of all-trans spheroidene in solution, where $\nu_4$ downshifts from 959 to 944 cm\(^{-1}\) when converted to the triplet state (33). This indicates that in these antenna complexes, carotenoid molecules do not change configuration when promoted to their triplet state, i.e., that their configuration is tightly locked by the protein environment.

In solution, upon triplet-state formation, the frequency of stretching modes of the conjugated C=Cs of the molecule dramatically downshifts from 1522 to 1494 cm\(^{-1}\) for $\beta$-carotene in tetrahydrofuran (THF) (30,36), or from 1529 to 1500 cm\(^{-1}\) for all-trans spheroidene in hexane (33), throughout the conjugated system (triplet high spin density hot spot is mainly in the center of the conjugated system) (33,37), which causes a reduction in the C=C bond order. The frequencies of the $\nu_1$ resonance Raman bands observed in protein-bound carotenoid triplet spectra are reported in Table 2 and there compared to those observed for triplet states of other carotenoids, including $\beta$-carotene in solution and spheroidene bound to the bacterial reaction center. The downshift depends on the carotenoid configuration, and it is always larger in cis configurations (29–33). For rhodopin glucoside in LH2, this downshift of the band from 1517 to 1493 cm\(^{-1}\) is very similar to that observed for all-trans $\beta$-carotene in solution (33,37).

Triplets compared are from rhodopin glucoside in LH2, lutein 1 (ground state of the latter from Ruban et al. (35)) and 2 in LHClI trimers and other carotenoid-containing complexes with all-trans-$\beta$-carotene, and other carotenoids, in solution (taken from (29–33,36)).
β-carotene and spheroidene in solution (24 cm\(^{-1}\) vs. 23–25 cm\(^{-1}\)). In contrast, the observed downshifts for this band for both luteins in LHII trimers, LHII monomers, CP29, and CP43 are much smaller and in all cases close to 18 cm\(^{-1}\), i.e., ~75% of the 23–25 cm\(^{-1}\) shift that is observed for all-trans carotenoid triplets in solution (see Table 2). Such a reduction of the \(v_1\) band’s downshift reflects a dramatic alteration of the nature of the triplet state, which correlates very well with a reduction in the energy gap between the \(S_0/S_2\) and \(T_1/T_n\) transitions observed for these carotenoids in LHII (see Table 1; it is harder to determine this gap with precision for CP43 due to the larger number of carotenoid molecules in this complex).

**DISCUSSION**

Our results are quite paradoxical at first sight. On the one hand, time-resolved absorption spectra show that no Chl \(a\) triplet is accumulated in LHII, whereas, on the other hand, the FTIR difference spectra strongly suggest the presence of Chl \(a\) contributions long after the initial excitation. To explain this apparent contradiction, the simplest hypothesis is that the triplet could be shared between carotenoid and chlorophyll molecules. This question has already been addressed in the literature (10). To explain the influence of the carotenoid triplet state on the absorption bands of the BChl molecules in LH complexes from purple bacteria, Angerhofer et al. proposed “a small delocalization of the carotenoid triplet over an adjacent BChl molecule” (10). They also noted that the apparent rate of (B) Chl to carotenoid triplet-triplet transfer seems to correlate with how much the carotenoid triplet state is able to influence the (B)Chl transition. However, it should be pointed out that in LH complexes from purple bacteria, the carotenoid and (B)Chl molecules are located very close to each other (an essential condition for triplet/triplet transfer), and therefore they each constitute a sizeable part of the environment (or solvation) of the other. It would thus be expected that the dielectric changes after the appearance of the carotenoid triplet state would have a measurable influence on the (B)Chl absorption transitions. Hence, these previous results (10) do not formally demonstrate a sharing of the triplet. In contrast, the resonance Raman spectra reported in this work provides a direct and unambiguous measurement of the sharing of the triplet of the carotenoid molecule. Indeed, upon sharing, the carotenoid triplet should progressively loose its pure triplet character, and the Raman signature of this state should become intermediate between the ground and triplet states. In the case of rhodopin glucoside in LH2 from *Rbl. acidophilus*, the downshift of the \(v_1\) band is quite similar to that of \(β\)-carotene or spheroidene in solution. We may thus safely conclude that there is very little, if any, wavefunction sharing between carotenoid and (B)Chl triplet states in the LH2 complex from *Rbl. acidophilus*.

In LHcs from higher plants, the presence of the triplet state of the lutein molecules is known to induce a net bleaching of the electronic absorption transition of the neighboring chlorophyll molecules (14). However, delocalization of the triplet was for a long time considered unlikely, due to the large energy gap between the triplet states of carotenoid and chlorophyll molecules (14). More recently, this position was challenged by time-resolved FTIR studies on peridinin-chlorophyll complexes, which demonstrated a co-existence of chlorophyll and carotenoid triplets throughout the entire triplet lifetime (27). Although the authors concluded that there could be a sharing of the triplet wavefunction between these two pigments, there is no other evidence for this conclusion apart from the contribution of chlorophyll spectral features during the carotenoid triplet lifetime. Here, we describe a similar situation in the LHII of higher plants. In this case, however, resonance Raman spectroscopy provides additional information on the nature of the carotenoid triplet in these complexes. The sensitivity of the \(v_1\) bands of the ground and triplet states is expected to exhibit similar responses to the environment. However, in LHII we observe a reduction of the energy gap between the \(v_1\) bands of the ground and triplet states by >30%. This indicates unambiguously that the electronic state gained by the carotenoid has lost a fraction of its carotenoid triplet character, and consequently, part of the triplet must be localized on another molecule. From the results of the step-scan time-resolved FTIR measurements (Fig. 2), we can safely conclude that a neighboring chlorophyll molecule is the acceptor of the carotenoid triplet. The fact that the same effect was found for both luteins to the same extent strongly substantiates this conclusion. Each lutein experiences a different protein environment (which induces the red shift of the electronic transitions of lutein 2 (38)) but is surrounded by a number of similarly positioned chlorophylls. The fact that both luteins exhibit the same 75/25 sharing of the triplet is thus most easily explained as a result of the pseudosymmetry of the position of these chlorophyll molecules (38). The same conclusion can be drawn for monomeric LHII, CP29, and CP43.

A closer analysis of the recently obtained time-resolved FTIR data obtained for the PCP peridinin triplet supports this analysis. In FTIR, the intensity and frequency of the bands arising from the vibrational modes of the triplet state should reflect the triplet sharing. Since most of the bands are distorted by the differential method and by overlapping contributions, an accurate determination of their precise intensity and frequency is difficult except in the case of well-isolated bands. In the case of LHII (Fig. 2), no carotenoid band can safely be used for that purpose. In the PCP spectra, the band arising from the stretching mode of the lactone carbonyl of peridinin is well isolated and contributes at ~1745 cm\(^{-1}\). From FTIR steady-state measurements of peridinin mixed with Chl \(a\) in THF (data not shown), the peridinin C=O lactone extinction coefficient was estimated.
to be similar to that of the Chl $a$ C=O keto group. This allows us to estimate the extent of the triplet sharing between peridinin and Chl $a$. It can be seen in Fig. 1 of Bonetti et al. (26) that the negative band area assigned to 9-keto C=O corresponds to ~25% and 40% of the negative band area assigned to lactone C=O for A-PCP and H-PCP, respectively. Taking into account the similar C=O extinction coefficient of peridinin lactone C=O and Chl $a$ 9-keto C=O, ~25% and 40% of the $^3$peridinin is shared with Chl $a$ in A-PCP and H-PCP, respectively. This conclusion is in good agreement with the relative amplitude of the $Q_y$ bleach as compared to the peridinin bleach of ~20% in the T-S spectra of A-PCP (39). This estimate of a 25% and 40% triplet sharing in A-PCP and H-PCP is also in line with the smaller observed bandshift of the carbonyl lactone for H-PCP (i.e., 20 cm$^{-1}$ as compared to 25 cm$^{-1}$ for A-PCP).

Thus, in contrast to photosynthetic bacteria, our results provide compelling evidence of triplet sharing between carotenoid and chlorophyll molecules in plant and algal light-harvesting complexes. It is obviously tempting to try to unravel which molecular mechanisms may be at the origin of this difference. In LH2, contacts between carotenoid and bacteriochlorophyll molecules essentially occur at the very end of the C=C conjugated chain of the carotenoid (Fig. 5 A, and McDermott et al. (40)), and the minimum distance between these molecules is 3.42 Å (41). In strong contrast, the closest contacts between Chl $a$ and luteins in LHCI occure at the middle of the C=C polyenic chain (Fig. 5 B), and the pigments are slightly more closely packed in these complexes. Taking into account the expected molecular structure of the carotenoid triplet state, the relative positioning of carotenoid and chlorophyll molecules in LHCI appears definitely more favorable for triplet sharing between these molecules.

To summarize, our results clearly show that the nature of the triplet excited state of carotenoid molecules are fundamentally different in the LH2 from $Rbl. acidophilus$ and the antenna isolated from spinach. In the former case, the triplet state is mainly (if not totally) localized on the rhodopin glucoside molecule. According to the work of Angerhofer et al. (10), this is the case for the vast majority of light-harvesting proteins from purple photosynthetic bacteria. This localization of the triplet state is associated with a relatively slow triplet-triplet transfer between the BCHl and carotenoid molecules, on the 20–200 ns timescale. In LHCI complexes from higher plants, there is a sharing of the triplet between luteins and their neighboring chlorophylls. As this is also the case in CP43 and CP29, as well as in PCP, it is likely that this triplet sharing exists in all light-harvesting proteins from plants and algae. This delocalization is associated with an ultrafast transfer/equilibration of the triplet between the chlorophyll and carotenoid molecules, which results in the absence of any measurable accumulation of pure triplet chlorophyll in these complexes. However, the price paid to avoid the accumulation of this species is that sharing of the triplet state between the chlorophyll and the carotenoid lasts for several microseconds. Apparently, such a mechanism drags the energy of the shared triplet below that of singlet oxygen. The resultant decrease in the probability of production of singlet oxygen thereby optimizes photoprotection of these complexes. It is striking that this tuning of photoprotection was found only in those organisms that perform photosynthesis in the presence of large amounts of molecular oxygen. We propose that triplet sharing represents an adaptation of the molecular mechanisms of protection against photooxidative stress, associated with the evolution of oxygenic photosynthesis.
