Patients’ pre-operative general and specific outcome expectations predict postoperative pain and function after total knee and total hip arthroplasties.
CHAPTER 6

Abstract

Background
One of the factors that may contribute to the variability in outcomes of total knee and hip arthroplasty (TKA and THA) are patients’ expectations about the outcome of surgery. However patients’ outcome expectations have rarely been included in prediction models aiming to predict postoperative outcomes.

Objectives
1) to examine whether patients’ preoperative outcome expectations predict function and pain 12 months after TKA and THA when assessed as one of the candidate predictive variables alongside other relevant clinical and sociodemographic variables. 2) to assess whether general outcome expectations or more specific outcome expectations better predict function and pain 12 months after TKA and THA.

Methods
A prospective cohort study on consecutive TKA and THA patients, with preoperative and 12 months after surgery outcome measures. Outcomes were the KOOS and HOOS (Knee or Hip injury and Osteoarthritis Outcome Score) activities of daily living and pain subscale scores. Patients’ outcome expectations were measured with the credibility expectancy questionnaire (CEQ) expectancy subscale which is a more generic expectations measure and the Hospital for Special Surgery (HSS) TKA and THA expectations surveys which queries expectations for specific functions and daily activities. Other candidate predictors were: preoperative pain and function, gender, age, education level, BMI, Kellgren and Lawrence score, mental health and treatment credibility. Prediction models were built using multivariate linear regression analysis with a backward selection procedure. Analyses were done separately for TKA and THA.

Results and conclusions
146 TKA patients and 148 THA patients were included in the analyses. Patients’ outcome expectations were consistently part of the combination of variables that best predicted outcomes for both TKA and THA. The amount of variance explained by the prediction models ranged between 17.0% and 30.3%, with higher scores on the expectation measures predicting better outcomes. However, the amount of variance explained by the expectation measures alone is limited. Therefore, we suggest that in planning surgical treatment orthopaedic surgeons should take a range of variables into account of which the patient’s expectations about outcome of surgery is one. Although the CEQ expectancy subscale predicted outcomes slightly better as compared to the HSS expectation surveys, differences in predictive value of the two measurements were too small to prefer the use of one of the two for prediction purposes.

Introduction
There is strong evidence that total knee arthroplasty (TKA) and total hip arthroplasty (THA) are cost-effective procedures for alleviating pain and increasing physical function in osteoarthritis patients. Although satisfaction rates are generally high, it is estimated that still 7-34% of patients are dissatisfied or report still having pain or physical limitations 6-12 months after surgery. The majority of these remaining complaints cannot be explained by technical factors like loosening of the prosthesis. As an increase of the number of joint arthroplasties is expected for the upcoming years, absolute numbers of patients with remaining complaints will thus probably also increase. Another recent development is that patients’ evaluations of care processes and outcomes play a prominent role in the financial compensations of hospitals. Both these trends make seeking pre-operative factors that can explain outcomes, resulting in a better selection of patients for surgery currently a priority in orthopedics.

One of the factors that may contribute to the variability in outcomes of TKA and THA are patients’ expectations about the outcome of surgery. Patients’ outcome expectations are defined as "improvements that patients believe will be achieved". Previously, studies in many fields have shown that these expectations are associated with outcomes. In TKA and THA however, mixed results have been found in studies examining the relationship between expectations and outcomes. In previous studies on patients’ expectations for TKA and THA the aim has been either to describe and quantify patients’ expectations or to investigate the association between preoperative outcome expectations and postoperative outcomes, or the association between fulfilment of expectations and outcomes. Statistical models presented in these articles have been mainly association models, in which the authors seek to estimate the relationship between expectations and outcomes as accurate as possible. For TKA and THA however many other factors have found to be also associated with outcomes, for example pre-operative pain and function, mental health, body mass index, comorbidity, age, female gender and radiological abnormalities. Probably a combination of these factors best identifies those at risk of poor outcome, rather than just one of these factors. So far, however, patient’s expectations have rarely been included as a candidate variable in multivariable prediction models for outcomes of TKA and THA. The first aim of this study therefore is to examine whether expectations have a predictive value when assessed as one of the candidate predictive variables alongside other clinical, demographic and psychosocial predictors that are commonly measured in clinical practice and have shown to predict post-operative outcomes.

Patients’ expectations are a multifaceted and complex construct, consequently measurement is challenging. Previous systematic reviews identified that patients’ expectations for TKA and THA are measured in many different ways. Some measurement methods are more targeted at very specific (functional) outcomes, while others assess expectations for outcome in a more general sense. Iles et al. found the
specificity of the expectation queried to be of influence on the strength of the association between expectations and outcomes. This may be one of the reasons of the variability in the results of the studies examining the relationship between expectations and outcomes in TKA and THA. Therefore, the second aim of this study is to assess whether specificity of the expected outcome assessed influences the predictive value of expectations on outcomes.

Methods

Participants and Procedures
This study was part of a larger prospective cohort study on patient reported outcomes of TKA and THA. The larger study included consecutive patients undergoing TKA or THA in the Rijnland Hospital in Leiderdorp, the Netherlands between October 2010 and September 2012. Assessments were done preoperatively and 12 months after surgery. From July 2011 until September 2012 patients participating in that study received additional pre-operative questions concerning pre-operative expectations about the outcome of surgery, hope and optimism. The larger study, as well as the extension was reviewed and approved by the local hospital Review Board of the Rijnland Hospital, Leiderdorp in the Netherlands (registration number 10/07).

The current paper reports on analyses done with the subset of patients that answered the additional questions. Consecutive eligible patients undergoing a primary TKA or THA were invited by their surgeon to participate in the study. Exclusion criteria were: revision surgery, hemi-arthroplasty, tumor or rheumatoid arthritis, a functioning limiting comorbidity (for example (hemiparesis), being not sufficiently competent in Dutch to complete a written survey, not being able to manage themselves or not having home care after surgery. Informed consent was obtained from the participants at the time of recruitment.

Assessments
One day prior to surgery all participants completed a survey including a number of sociodemographic, disease characteristics, patient expectations questionnaires and a number of patient reported outcome measures (PROMs). Approximately 12 months after surgery a survey assessing the same PROMs as pre-operatively was sent to the patients’ home address together with a pre-stamped return envelope. If the patient did not return the survey within 3 weeks, we attempted to contact the patient by phone and if necessary we sent another copy of the survey to the patient.

General outcome expectations and treatment credibility
Expectations about general recovery after surgery were assessed with the expectancy subscale of the Credibility Expectancy Questionnaire (CEQ) which contains three items that are scored on a 0–9 scale and hence the sum score ranges from 0–27\(^\text{35,36}\). In each of the items the word ‘therapy’ was replaced by ‘surgery’. An example of an item is “How much do you really feel that the surgery will help you to reduce your symptoms” Next to outcome expectations the CEQ also contains a credibility subscale. Credibility is defined as “how believable, convincing and logical the treatment is” this concept is closely related to outcome expectations. The credibility subscale also which contains three items that are scored on a 0–9 scale and hence the sum score ranges from 0–27.

Specific outcome expectations
Outcome expectations for 19 (TKA) or 20 (THA) specific outcomes with regard to function and pain of hip or knee (eg, walking stairs, pain during daytime) were measured with the Hospital for Special Surgery Knee and Hip Replacement and Knee Replacement Expectations Surveys\(^\text{35,36}\), from here on referred to as the HSS expectation surveys (separate questionnaires for TKA and THA). Answering options for all items are scored on a 0–4 scale (4= back to normal, 3=much improvement, 2=somewhat improvement, 1=small improvement, 0= don’t have this expectation). Principal component analysis with an oblique rotation was used to derive a coherent expectations for post-operative ‘function’ variable from the items of the HSS expectation surveys. For TKA items about walking stairs, getting rid of limp, getting in or out of bed chair or car, be able to put on shoes and socks, improve ability to do daily activities in and around the house and improve ability to cut toenails were summed into an ‘expectations for function’ scale. For THA the sum of two items namely relieve of pain during the day, relieve of pain during the night was used as the ‘pain expectations’ scale. Because this variable was highly skewed it was dichotomized in ≤3 and >7 points For TKA the items about being able to stretch the knee, walking stairs, kneeling down, traveling with public transportation, improving ability to do daily activities in and around the house and being able to change position (sitting down, getting up etc.) were summed into an ‘expectations for function’ scale. For TKA the HSS expectation survey only contains one pain item which was used as ‘pain expectations’ scale, this item was highly skewed and therefore it was dichotomized in ≤3 and 4 points.

Pain and function
Pain and function were measured both pre-operatively and 12 months post-operatively. For patients undergoing TKA pain and function were measured with respectively the pain and ADL subscales of the Dutch version of the Knee injury and Osteoarthritis Outcome Score (KOOS)\(^\text{37,38}\). The pain subscale consists of 9 items and the ADL subscale consists of 17 items, all items have five possible answer options scored from 0 (no problems) to 4 (extreme problems) and each subscale score is calculated as the sum of the items included. Scores are transformed to a 0–100 scale, with 0 representing extreme knee problems and 100 representing no knee problems\(^\text{38}\). For patients undergoing THA pain and function were measured using respectively the pain and ADL subscales of the Dutch version of the Hip injury and Osteoarthritis Outcome Score (HOOS)\(^\text{39}\). The pain subscale consists of 10 items and the ADL subscale consists of 17 items, answering options and calculation of subscale scores are the same as for the KOOS. The KOOS and the HOOS have proven to be valid and reliable measurement instruments for patients undergoing respectively TKA and THA\(^\text{37,39}\).
Quality of life was measured with the Short Form 36 (SF-36), from which the Mental Component Score (SF-36 MCS) was calculated and a Physical Component Score (SF-36 PCS) was calculated. These summary scores of the SF-36 have shown to be valid and reliable in many different populations, scores range from 0-100 with a higher score representing better quality of life.

Preoperative radiological severity
Preoperative supine radiographs of hips (anterior-posterior) and weight-bearing radiographs of the knee (posterior-anterior) were collected from the patients’ medical record. These radiographs were routinely made in the participating center for preoperative templating purposes. All radiographs were assessed by an experienced radiologist who was blinded for the side of operation and patient characteristics. The Kellgren and Lawrence (KL) grading system was used to classify the severity of OA (grade 0: indicating no OA; grade 1: doubtful OA; grade 2: minimal OA; grade 3: moderate OA and grade 4: indicating severe OA). 10% of the radiographs were scored twice: correlation between both readings were used to establish intra-reader reliability (Intra-Class Correlation hip radiographs: 99% (95% CI: 85-93%); Intra-Class Correlation knee radiographs: 95% (95% CI:92-98%). The KL grade in our study was classified as mild in KL 0-2 and severe in KL 3-4.

Sociodemographic variables and patient characteristics
Education level was scored on a 8-point scale with answering options representing the education levels in The Netherlands, scores were dichotomized in low level (no education, primary school, lower general secondary school, lower vocational education) versus high level (intermediate vocational education, higher general secondary school, higher vocational education, university). Self-reported weight and height were used to calculate Body Mass Index (BMI).

Analyses
Multivariate linear regression analyses were employed with postoperative pain (KOOS/HOOS pain) and function (KOOS/HOOS pain) as dependent variables. Besides the expectation related variables (general outcome expectations, specific outcome expectations and credibility) we selected 7 variables measured preoperatively as candidate predictors of outcome namely preoperative pain, preoperative function, gender, age, education level, BMI, Kellgren and Lawrence score (KL-score), mental health. The selection of these candidate predictors was based on discussions with orthopaedic surgeons about which predictors of outcome they consider in daily practice.

A backwards elimination method was used for these analyses. This procedure started with including all candidate variables in the model, subsequently the least significant variable was removed (the one with the highest p-value). The model was thereafter refitted without this variable, and again the least significant variable was removed. This process was repeated until all predictor variables in the model had a p-value < 0.10.

The models were first ran with the CEQ expectancy subscale as the expectations variable, in case that the CEQ expectancy subscale was included in the final model, this final model was repeated while replacing the CEQ expectancy subscale with the HSS expectation survey subscale corresponding to the outcome of that model (so the HSS expectation function score was used for the models with function as the dependent variable and the HSS expectation pain score was used for the models with pain as the dependent variable). If the CEQ expectancy subscale was not included in the final model, the backwards elimination procedure was completely repeated with the HSS expectation survey score as a candidate predictor instead of the CEQ expectancy score. The R2 values of the final models were then compared to assess the differences between predictive ability of the models with generic CEQ expectancy subscale and the models with the more specific HSS expectation survey score. All analyses were performed with IBM SPSS Statistics 20 and were done separately for TKA and THA.

Results
Flow of patients and characteristics of the sample
Between July 2011 to September 2012 189 THA and 186 TKA patients were enrolled in the study and completed the additional questions on outcome expectations. In the current study the patients from this subgroup that returned the follow-up questionnaires (146 TKA patients and 148 THA patients) are included. TKA patients included in this study had a mean age of 66.9 years (SD 9.2) and 69% was female, THA patients included in this study had a mean age 67.2 (SD 9.5) and 57% was female. Both the characteristics of the total sample and the subsample included in the current analyses are described in Table 1. The characteristics (age, gender, baseline HOOS and KOOS scores) of the subsample of patients included in current analyses did not differ from those of the total study sample.
The predictive value of outcome expectations for Total Knee Arthroplasty

Multivariate linear regression models identified BMI, better mental health (SF-36 mental component summary), baseline function (baseline KOOS ADL subscale) and patients’ general expectations of outcome (CEQ expectancy) as significant predictors of a better (function) KOOS ADL score 12 months post TKA (Table 2). The final model explained 30.3% ($R^2$ 0.303) of the variance in outcome. When the CEQ expectancy score was replaced by the more specific expectations measure HSS expectation function subscale the explained variance decreased to 25.2% ($R^2$ 0.252).

For the outcome pain 12 months after TKA, BMI, mental health and patients’ general expectations of outcome (CEQ expectancy) were identified as significant predictors (Table 3). The final model explained 17% ($R^2$ 0.170) of the variance of the postoperative pain. When the CEQ expectancy score was replaced by the more specific HSS expectation pain subscale the variance explained slightly improved to 17.7% ($R^2$ 0.177).

The predictive value of outcome expectations for Total Hip Arthroplasty

Multivariate linear regression models identified baseline function, the KL-score and patients’ general expectations of outcome (CEQ expectancy) as significant predictors of function 12 months after THA (Table 4). The final model explained 18.6% ($R^2$ 0.186) of the variance in outcome. When the CEQ expectancy score was replaced by the more specific expectations measure (HSS expectation surveys function subscale) the explained variance slightly decreased to 17.7% ($R^2$ 0.177).

For the outcome pain 12 months after THA, baseline function, the KL-score and patients’ general expectations of outcome (CEQ expectancy) were identified as significant predictors (Table 5). The final model explained 18.4% ($R^2$ 0.184) of variance in the outcome. When the CEQ expectancy score was replaced by the more specific expectations measure (HSS expectation surveys pain subscale) the explained variance was similar (18.3% ($R^2$ 0.183)).

Discussion

The primary findings of the analyses were 1) that patient expectations for the outcome of THA and TKA consistently are part of a prediction model that predicts the outcomes pain and function 1 year post-operative. 2) that the more general CEQ expectancy subscale explains slightly more variance in function in TKA and function and pain in THA as compared to the HSS total knee or total hip arthroplasty expectation surveys.

This study is, to the best of our knowledge, the first to assess the predictive value of expectations within a prediction model in which multiple other clinical and sociodemographic variables were entered; we however do want to discuss our results in the light of previous findings regarding patients’ outcome expectations for TKA and THA. Several studies have been published that examine the association between pre-operative expectations and outcomes of TKA and THA. These studies analyze their data from an etiological perspective, the aim those studies is to determine whether a particular independent variable really affects the dependent variable, and to estimate the magnitude of that effect. Thus, in such studies patients’ expectations are the determinant of interest while other variables are regarded as confounders of the relationship between patients’ expectations and outcomes. For these studies contradictory results are found; some studies show a positive associations which suggest that higher expectations are related to better outcomes, others find no association or even negative associations.

This variability in results of studies may be caused by the type of expectations examined, the measurement approach used, the outcome assessed, the timing of the outcome assessment or the use of univariate versus multivariate statistical methods. These studies however do not answer the question as to whether patient’s expectations can be used in clinical practice to predict the clinical course of the disorder. To answer this question one has to examine whether the predictive value increases by including the expectation variables in the regression analysis. Our study does answer that question by examining expectations within prediction models which “seek to get optimal predictions based on a linear combination of whatever variables are available”. In our study we chose to include candidate variables in the multivariate models that mimic clinical routine, i.e. are easily accessible for professionals because they are already part of regular anamnesis and routine outcome measurement. Our study showed that expectations consistently are part of the set of variables that together best predict the outcomes function and pain 1 year after TKA and THA. Post-hoc we assessed for each model what the amount of explained variance that could be attributed to the expectations measure by running the final prediction models again without the expectations variable and subtracting the $R^2$ of these models from the $R^2$ of the final models described in the results section. The amount of variance explained by expectations alone ranged from 1.3% to 6.5%. Thus, although expectations seem important, they only account for a limited amount of the variance in outcomes. Despite the relatively low amount of variance explained we still think that routinely assessing patients’ expectations in clinical practice is advisable because besides this limited predictive role discussing patients’ expectations for TKA and THA has more functions in treatment setting. Assessing and discussing patient’s expectations is also valuable for patient-practitioner communication and shared decision making. It is further suggested that patients’ expectations may be a factor that is causally related to treatment outcome. This could imply that through altering expectations one would be able to achieve better treatment outcomes. Although experimental research with healthy volunteers seems to point in this direction, clinical research has not confirmed this as RCT’s are scarce and observational studies have found mixed results and cannot fully establish causality. Furthermore, it is still unclear what the most optimal expectation is in clinical situations. Should an expectation be high in order for the non-specific or placebo effects of the intervention to be optimal, or should high expectations for instance be tempered to prevent disappointment?

The second research question of this study examined whether the measurement approach used to measure expectations influenced the predictive value of expectations. Results showed that expectations that were measured with the more general CEQ expectancy subscale predicted most outcomes slightly better than the more outcome specific HSS expectation surveys, specifically for the outcome functioning. However, the differences in predictive value between the CEQ and HSS expectations survey are too small to give a definite answer to the question which one better predicts outcomes. Results do not correspond to those of Iles et al. who found that the more specific the items of a questionnaire were, the better the predictive value for that outcome. A recent systematic review distinguished between measurement instruments that measured the importance of expectations and measurement instruments that measured the probability that certain events would happen. This review found that measurement instruments that measured probabilities showed better associations with outcomes. It seems like the construct patients’ expectations has multiple dimensions that can be measured. In current measurement instruments different combinations of these dimensions are incorporated. Our study assessed whether variations in only one dimension of expectations (specificity of the expected outcome) accounted for differences in predictive values. Further research is needed to identify which dimensions of the construct ‘patients’ outcome expectations’ need to be included in the optimal measurement instrument.

This study has several strengths. Firstly, all questionnaires used in this study are well known validated measures that are used in research as well as clinical practice. Secondly, patients were recruited consecutively from one general hospital in the Netherlands. The latter is the setting were most TKA and THA surgeries are performed. The characteristics of our sample are not only comparable to the THA and TKA population of the larger VESPA study but also very similar to the overall Dutch population of TKA and THA patients in 2011 and 2012 which are described in the Dutch Arthroplasty Registry Report 2012 ensuring generalizability of our results. The latter has a nationwide completeness of all THA and TKA of 97-98%.
We chose our candidate variables for the multivariate models based on two criteria; variables had to be associated with outcomes of TKA or THA in previous studies, furthermore they (which is recommended also by several authorities in orthopedics) and had to be simple and reliable measures that are already commonly used in clinical practice. A limitation of this study is that because of the sample size, the number of candidate variables that could be examined was limited. It may therefore be that we have missed important predictive variables. A strength of this study is the use of a continuous predictors and outcome measures. Although some may argue that for clinical practice it is more useful to use dichotomous outcomes and define cut off values for the predictors in the study several methodological studies also have suggested that it is better to not dichotomize in prediction studies as continuous variables contain more information and model fit generally is better with continuous variables^{52, 53}. Further, because patient acceptable symptom states have not been established yet for the HOOS and KOOS measures and therefore any cut off point for the outcomes used in this study would be arbitrary. Lastly, to answer the second research question it was necessary to calculate a summary score for the pain and function expectation items of the HSS expectation surveys. However, these questionnaires were developed for the use of the individual item scores, and although in literature all items have been summed before into one total score, factor structures have not been developed officially yet. We therefore did exploratory factor analyses to derive comprehensive ‘expectations about function’ factors. As only one (THA) or two (TKA) items are about pain, we did not run a factor analyses for those items but dichotomized them to get a proper distribution of answers.

In conclusion, patients’ outcome expectations were consistently part of the combination of variables that best predicted function and pain 12 months postoperative for both TKA and THA. However, the amount of variance explained by the expectation measures alone is limited. Therefore, we suggest that in planning surgical treatment orthopedic surgeons should take a range of variables into account of which the patient’s expectations about outcome of surgery is one. Although the CEQ expectancy subscale predicted outcomes slightly better as compared to the HSS expectation surveys, differences in predictive value of the two measurements were too small to prefer the use of one of the two for prediction purposes. Future studies are advised to replicate these findings and externally validate the models presented.
